Military medicine

Definition

Military medicine may be defined in several ways: 1) as a branch of medicine concerned with the healthcare needs of military personnel on active duty, whether in combat zones or stateside; 2) as battlefield medicine, concerned with the triage and treatment of mass casualties of war; 3) as the provision of health care for service members, their dependents, and veterans during peacetime; or 4) as a branch of research and development related to matters of military interest. These matters include sanitation and disease prevention; evacuation of casualties; special health issues related to aviation, space flight, or underwater deployment; or mental health issues related to military service. Military medical research has often proved beneficial to the civilian population, particularly in the control of infectious diseases, the development of emergency medical services, improvements in surgical technique and equipment, and the management of terrorist attacks and mass transportation or industrial disasters.

Description

Military medicine has evolved over a period of several thousand years from emergency treatment of wounded soldiers or sailors in ancient Egypt, Greece, and Rome to an organized system of preventive as well as interventional health care in all modern militaries. All medical, surgical, dental, and veterinary specialties are represented in contemporary military health services, and most developed countries have specialized medical schools for post-college and postgraduate training of their medical corps.

Origins

The oldest aspect of military medicine, and the one with which most people are familiar, is battlefield medicine, the emergency treatment of those wounded in combat. In ancient Egypt and Greece, battlefield treatment was relatively informal; these armies did not have dedicated medical corps (although the Egyptian pharaohs did pay physicians to attend wounded soldiers). Wounded men were either allowed to remain where they fell until the battle was over, or their comrades might carry them back from the field. Medical care of prisoners was nonexistent; fleeing soldiers were slaughtered as they ran rather than taken prisoner by the victorious army. Because combat was largely hand-to-hand in the ancient world, battlefields covered relatively small areas in comparison to those of later wars, so evacuation of the wounded was not a priority. The weapons used prior to the invention of gunpowder resulted primarily in cuts, penetrating injuries, or simple **fractures**. While these were indeed often fatal, the kinds of disfiguring or dismembering injuries inflicted by high-power artillery, blasting agents, ionizing radiation, or chemical agents were unknown.

A military camp hospital in Afghanistan. *(Horizons WWP / Alamy)*

The first army to have a permanent educated medical corps was the Roman army under Augustus Caesar (63 B.C.–14A.D.). Augustus established a medical school to train surgeons for the army and drew up manuals to standardize treatment. Each legion had several educated physicians, one for every 600 soldiers, who were known as *medici legionis*. They were responsible for sanitation in the army camps, **physical examination** of army recruits, and veterinary care of horses and pack animals as well as care of the sick and wounded humans. The Roman military surgeon had the best equipped instrument kit in the ancient world. Other innovations of the Roman army's medical system included the mobile military hospital, or *valetudinarium*, to treat the sick or injured inside the camp. Some of these hospitals could accommodate as many as 200 patients at one time and were laid out with consideration for hygiene as well as comfort. The other major innovation of Roman military medicine was the combat medic, a soldier who was not a licensed physician but was given limited medical training and what moderns would call first-aid supplies to assist wounded soldiers on the battlefield.

Advances in military medicine are generally made in response to advances in weaponry. This principle is well illustrated by the introduction of gunpowder into European warfare in the fifteenth century. The guns and cannon of the early modern period did not have longer ranges than the Roman *ballista*, a siege catapult that could throw heavy rocks about 500 yards, or the English longbow, whose arrows could pierce medieval plate armor at 320 yards. (For comparison, the Springfield rifle of the Civil War era and the M-1 Garand of World War II had the same accurate range as the Roman siege machine, 500 yards). What was different about the early guns and cannon was the type of injuries they inflicted. Almost all gunshot **wounds** became severely infected by clothing and debris forced into the wound by the bullet itself or by the unwashed hands of the surgeon trying to remove the bullet. In addition, bullets could shatter bones, and cannon balls could slice off entire limbs. **Amputation** became increasingly necessary to treat wounded soldiers, but death from **shock**, if not infection, often followed.

CLARA BARTON (DECEMBER 25, 1821–APRIL 12, 1912)

Clara Barton. *(Courtesy of the Library of Congress, Copyright 1904 by JE Purdy, Boston)*

Clara Barton was interested in the medical profession from an early age. During the Civil War, she was omnipresent on the front line, providing necessary aid and supplies to soldiers. She also provided emotional support, praying with them and listening to them. After the Civil War, Barton went to Europe and was introduced to the Red Cross Organization. She realized a need for a disaster relief organization in the United States.

In 1881, Barton led a group in the creation of the American Red Cross. In that same year, the organization was utilized when Michigan experienced tragic forest fires. Barton organized relief efforts, sending clothes and food to the victims of the fires. The American Red Cross also helped those in need outside of the United States.

The American Red Cross is still very involved in disaster assistance, helping people with emergency preparedness and those who have suffered devastation.

Improvements in the range and firepower of artillery had the side effect of increasing the size of the battlefield as well as the severity of the injuries inflicted on combatants. By the time of the Napoleonic Wars (1792–1815), most European armies had cannon and howitzers with maximum ranges of close to a mile. American Civil War cannons had a range of about 1,440 yards. The longer distances from the front line to the rear of the army demanded greater attention to the evacuation of the wounded. The first organized ambulance corps in a European army was introduced by Dominique Jean Larrey (1766–1842), the surgeon general of Napoleon's Grande Armée. Larrey developed a corps of horse-drawn ambulances to move the wounded to field hospitals as quickly as possible, and he also introduced the first system of triage, or sorting casualties according to the severity of their wounds and the urgency of their need for treatment. Larrey also followed an agreement that had first been made following the battle of Dettingen in 1743, whereby the opposing armies agreed that wounded soldiers who fell into the hands of either side would be given medical care on equal terms with their captors. This principle still holds true in military medicine: Medical personnel are expected to treat injured prisoners of war as well as their own wounded.

Military medicine in the United States

Military medicine in the United States evolved over the history of the nation from a small wartime-only organization to a widely diversified and specialized network of hospitals, clinics, medical and dental schools, training facilities, and research centers. It dates from July 1775, when the Army Hospital was established to provide medical care for soldiers in the Continental Army. The medical service existed only in wartime until 1818, however, when Congress established a permanent medical department, later known as the Army Medical Department or AMEDD. The medical department of the Army served the needs of all branches of the military until 1871, when the Navy formally established its own medical corps. World War I (1914–1918) and World War II (1939–1945) required the expansion and significant reorganization of both services' medical departments. The Air Force, which did not become a separate branch of the military until 1947, established its own medical service in 1949.

AMEDD, the oldest component of the Military Health System (MHS), had six branches as of 2014: the Medical Corps, which traces its beginnings to 1775; the Army Nurse Corps (1901); the Dental Corps (1911); the Veterinary Corps (1916); the Medical

Service Corps (1917); and the Army Specialist Medical Corps (1947). The U.S. Navy and the U.S. Air Force have separate medical corps, nurse corps, dental corps, and medical service corps; the Army Veterinary Corps provides veterinary services to all branches of the U.S. military. Medical care for members of the Coast Guard is provided by commissioned officers of the U.S. **Public Health** Service; the Coast Guard does not have its own dedicated medical corps. Similarly, medical care for members of the Marine Corps is provided by the U.S. Navy's medical, nursing, and dental personnel.

Purpose

Combat medicine

Combat or battlefield medicine refers to emergency treatment of wounded soldiers, sailors, or airmen at the location of the injury. The so-called father of battlefield medicine is generally considered to be Ambroise Paré (1510–1590), a surgeon with the French army who devised more effective ways to treat gunshot wounds and prevent infection, as well as safer methods of limb amputation. The use of combat medics to treat the wounded before they could be transported to an aid station or field hospital was reintroduced by the U.S. Army during World War I. Two enlisted men in each company were given training in **first aid**, including the splinting of fractures and control of hemorrhages. In World War II, American medics began to participate in triage as well as administering first aid; their tasks included administering **tetanus** booster shots and administering oral **antibiotics** in addition to the use of tourniquets to control bleeding.

As of 2014, medics received a 16-week training course that brought them up to the level of an emergency medical technician (EMT), basic level. The skills required are mostly noninvasive, including positive pressure ventilation with an air bag mask, airway support, and supplemental oxygen administration as well as splinting and bleeding control. After 2008, training was combined for army, navy, and air force medics into a single program (with some service-specific instruction) given at the Medical Education and Training Campus (METC) at Fort Sam Houston in Texas.

Evacuation of casualties

Dominique Jean Larrey's innovative use of horse-drawn ambulances to evacuate battlefield casualties was introduced into U.S. military medicine during the Civil War by Jonathan Letterman (1824–1872), medical director of the Army of the Potomac. Following the Battle of Antietam in 1862, Letterman instituted an efficient system of triage, horse-drawn ambulances, and forward first aid stations that greatly reduced mortality. After the Battle of Gettysburg in 1863, Letterman was able to report that all casualties had been evacuated from the battlefield within six hours, and all wounds treated within a day—a remarkable accomplishment for that time.

The introduction of motorized vehicles and airplanes into combat in World War I added new possibilities for efficient evacuation of the wounded as well as new terrors to the battlefield. Although the airplanes of World War I were not yet capable of carrying more than their own aircrew, motor vehicles quickly proved to be effective ambulances. By the time of World War II, airplanes were large and powerful enough to serve as airborne ambulances, with flight surgeons and flight nurses as well as medics. The army's first air ambulance squadron was formed at Fort Benning in Georgia in 1942, followed by the formation of helicopter evacuation units during the Korean War (1950–1953) and the Vietnam War (1955–1975).

The evolution of combat medicine and medical evacuation has benefited the civilian population by its role in the formation and growth of emergency medical services. During the Korean War, some physicians in the Chicago area began to ask why the principles of military medical care could not be applied to emergency treatment of injured civilians. The Chicago Fire Department began the first **trauma** training program for first responders, which grew by the 1980s into programs for emergency medical service (EMS) professionals who could provide prehospital care and **life support** as well as transport people to hospitals. Many of the first certified EMS professionals were combat veterans of the Vietnam War. The School of Medicine of the Uniformed Services University of the Health Sciences (USUHS) combines military medicine and emergency medicine in a single department.

Sanitation and disease control

Armies have been aware since Roman times of the importance of sanitation and personal cleanliness in army camps even before the germ theory of disease was developed. Disease killed more combatants than weaponry until World War II, the first war in history in which the reverse was true. It is significant that George Washington's 1777 instructions to the soldiers of the Continental Army emphasize the importance of good hygiene to health and underscore the role of the medical officer in enforcing standards of sanitation.

The connection between sanitation and disease control became increasingly clear after the discovery of the germ theory of disease in the late nineteenth century. Walter Reed (1851–1902), a physician with the U.S. Army Medical Corps, became famous for his work with **yellow fever**, tracing its spread to mosquito

WWW.BOOKBAZ.IR

bites, a discovery that led to the successful completion of the Panama Canal as well as the virtual eradication of yellow **fever** in the developed countries. Considered a milestone in epidemiology and public health, Reed's work led to the establishment of military research facilities in infectious diseases, including an HIV research program and a program to develop a **malaria** vaccine as of 2014 headquartered in Silver Spring, Maryland.

Combat-related mental health issues

The Civil War was the first war in U.S. history to provide documentary evidence of the traumatic effects of combat on the human psyche. A 2006 study of the medical records of 17,700 Civil War veterans revealed how many of these survivors suffered from what were termed nervous disorders by the nineteenth-century physicians who treated them after the war. Symptoms included **paranoia**, **psychosis**, **hallucinations**, illusions, **insomnia**, confusion, **hysteria**, memory problems, **delusions**, and violent behavior. These so-called nervous disorders were collectively termed shell shock in World War I veterans and combat **stress** reaction or battle **fatigue** in veterans of World War II, but the symptoms were similar to those of their Civil War counterparts.

It was not until the Vietnam War that posttraumatic stress disorder (PTSD) in combat veterans was codified as a formal psychiatric diagnosis and added to the third (1980) edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). By the time of the fourth edition (DSM-IV) in 2000, the diagnostic criteria for PTSD took into account its occurrence in the civilian population as well. Many of the treatments for PTSD that resulted from the experience and research of military psychiatrists have proved beneficial to civilian survivors of mass disasters, terrorism, criminal assault, and other traumatic events.

Research

Although some research into different types of weaponry and tactics has always been conducted (the Romans were adept at borrowing previously unfamiliar weapons and tactics from their opponents), organized scientific research into weapons of war, extreme environments, chemical and biological weapons, and their effects on humans is largely a product of the twentieth and twenty-first centuries. Although the numbers of medical doctors in the military assigned to research is small compared to those in clinical practice, the following areas of research are still considered important:

- Aerospace medicine, also called flight medicine or aviation medicine, is a specialized field of occupational medicine in which the physiological and psychological stresses on humans in flight are studied. Physicians in this specialty also examine flight crews, astronauts, and civilian pilots for physical and psychological fitness. Research in aerospace medicine is conducted at the U.S. Air Force School of Aerospace Medicine (USAFSAM) at Wright-Patterson Air Force Base in Ohio.
- Diving medicine, also called undersea and hyperbaric medicine, is a specialized field of occupational medicine that studies the prevention and treatment of diving accidents, the hazards of the marine environment, and the effects of physiological changes underwater on the diver's judgment and psychological fitness to dive. The U.S. Navy first began to research decompression sickness in 1912 and established an experimental diving unit in 1927. Most military research in hyperbaric medicine is still conducted by the Navy.
- Defenses against biological warfare: Research into disease agents that could be used as weapons of bioterrorism (such as smallpox, anthrax, and bubonic plague) is conducted at the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID). USAMRIID began in the 1950s as the Army's Biological Warfare Laboratory (BWL). Located at Fort Detrick in Maryland, the facility is known for its frequent collaboration with the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) in the development of vaccines and treatments for tropical diseases. It is also well known for its work with Ebola fever.
- Defenses against chemical warfare: Research into the pharmacology, toxicology, physiological effects, and biochemistry of chemical agents is conducted at the U.S. Army Medical Research Institute of Chemical Defense (USAMRICD) at Aberdeen Proving Ground in Maryland. The institute also works to develop treatments and countermeasures for persons injured by chemical warfare agents. USAMRICD and USAMRIID together offer training courses for healthcare personnel in the medical management of casualties of chemical or biological agents.
- Posttraumatic syndromes and other mental health issues that affect military personnel are studied at the Center for Military Psychiatry and Neuroscience, part of the Walter Reed Army Institute of Research (WRAIR) in Maryland. Founded as the Army Medical School in 1893, WRAIR is the oldest school of public health and preventive medicine in the United States.

KEY TERMS

Combat medic—A soldier, sailor, or airman who is not a medical doctor but has received basic EMT training and is responsible for providing first aid and frontline trauma care on the battlefield.

Triage—A system for determining the priority of patients' treatment according to the severity of their injuries in mass casualty situations when it is not possible to treat all patients at once. Triage may be used to prioritize emergency treatment, emergency transport, or the destination of emergency transport.

Preparation

Preparation for service in military medicine may be undertaken along several different educational paths. Undergraduates who are completing a B.S. degree in nursing may be eligible for financial assistance and a stipend if they complete their degree, pass the NCLEX certification examination, and are physically qualified for military service. Undergraduates who are applying to accredited schools of medicine, dentistry, optometry, psychology, or veterinary medicine may be eligible for a scholarship that pays their full tuition plus a monthly stipend. They are then required to spend one year in active military service for each year that they received the scholarship. Undergraduates interested in careers in military medicine, nursing, or dentistry may also apply to the Uniformed Services University of the Health Sciences (USUHS) in Bethesda, Maryland, which includes a medical school, school of dentistry, nursing school, and graduate school of nursing.

People who have already completed their M.D. or D.O. degree may apply to be placed in military residency programs in order to train for a specialty or subspecialty. The army maintains 11 training hospitals and three institutes and also sponsors specialized fellowships in civilian medical centers, including Duke, Johns Hopkins, Yale, and Stanford universities.

Enlisted men and women may enter specialized training that prepares them for work as combat medics, pharmacy assistants, laboratory technicians, EMTs, **radiology** technicians, and medical equipment specialists.

Risks

Some specialties in military medicine, such as **aviation medicine**, diving medicine, and research in biological or chemical agents are riskier than most civilian medical specialties because of the severity of possible work-related accidents from equipment failure or exposure to radiation, chemical agents, or pathogenic viruses or bacteria. Battlefield medicine is the riskiest because of the potential for severe injury, death, or capture by the enemy.

Military mental health

Definition

Military health care, or **military medicine**, is not recognized as a specialty by the American Board of Medical Specialties (ABMS); nonetheless, it is a distinctive category of medical and psychiatric practice. In the twenty-first century, military medicine involves routine health care (including mental health care) for military personnel and their dependents, but it also includes battlefield treatment and evacuation, disease prevention, disaster relief, health care for military personnel in such extreme environments as deserts and the polar regions, and research in these fields—including mental health research. Aerospace medicine and undersea medicine are newer subspecialties that have developed within the larger field of military medicine.

Military physicians are often stationed with the troops they serve, and they must be acquainted with unusual diseases, traumatic injuries, and psychological stressors that are rarely encountered in civilian settings. The Borden Institute of the U.S. Army Medical Department was founded in 1987 to publish textbooks of military medicine on topics ranging from chemical warfare and health care in harsh environments to preventive medicine and medical ethics. As of 2011, the Institute had published 20 separate textbooks; volumes 5 and 6 are titled *Military Psychiatry* and *War Psychiatry*, respectively.

Military suicide rates

(Graph by PreMediaGlobal. © Cengage Learning®.)

Veterans' health care in the United States dates back to the Revolutionary War, when the first federal military hospital, Hand Hospital, was opened in Pittsburgh in 1778. Contemporary veterans' health care includes a range of different services, from post-deployment counseling and routine medical checkups to inpatient medical and mental health care, including hospice care. The Department of Veterans Affairs (VA) system is currently divided into 21 geographical regions known as Veterans Integrated Service Networks or VISNs. These regions include both VA hospitals and Vet Centers, which are run by the Veterans Health Administration (VHA), and community-based outpatient clinics staffed by civilian physicians who work in partnership with the VA.

Demographics

U.S. military personnel on active duty are under the care of the Military Health System (MHS), which covers approximately 9.5 million beneficiaries, including the families of active duty personnel as well as retirees and their families. The MHS has about 137,000 employees and an annual budget of $42 billion; it operates 65 hospitals, 412 clinics, and 414 dental clinics at facilities across the United States and around the world, as well as facilities in overseas combat theater operations. The health benefits program for active duty personnel, their dependents, and retirees using civilian healthcare providers is known as TRICARE.

The MHS also operates the Uniformed Services University of the Health Sciences (USU), a graduate university established in Bethesda, Maryland, in 1972 that includes a medical school, dental school, school of nursing, and graduate school in the biomedical sciences offering PhD and DPH degrees. USU had about 850 students enrolled in all its graduate programs as of 2011.

Veterans are eligible for benefits from the Veterans Benefits Administration (VBA), depending on their membership in one of eight priority groups. Those retired from long-term military service, those with service-related injuries or conditions, and those awarded the Purple Heart are in the higher-priority groups. Veterans without service-related conditions are eligible for treatment on the basis of financial need. In 2010, there were one million veterans receiving disability benefits, most of them from the period of the Vietnam War (1954–1975).

Description

Historical background

Military medicine and veterans' benefits both originated with Augustus Caesar (63 B.C.–14 A.D.), the

Demographic characteristics of Operation Iraqi Freedom (Iraq) and Operation Enduring Freedom (Afghanistan and surrounding regions) veterans newly utilizing VA healthcare services between October 7, 2001, and March 31, 2007, followed until March 31, 2008, by mental health category

Characteristic	Total veterans	Veterans with no mental health diagnosis		Veterans diagnosed with mental health disorders other than PTSD*		Veterans diagnosed with PTSD*

first emperor of Rome. Augustus reorganized the Roman army, putting it on a professional footing and creating the first dedicated medical corps in military history. He established a medical school for the training of army physicians (who were responsible for veterinary care for the army's horses and pack

WWW.BOOKBAZ.IR

animals as well as surgery and medical care for the soldiers), who had to pass detailed course work and examinations to be allowed to join the army. Other innovations were the formation of special groups of soldiers tasked with retrieving the wounded from the battlefield; construction of permanent hospitals (*valetudinaria*) within the army's fortified camps, with special **isolation** rooms for soldiers with infectious diseases; and the establishment of medical specialties within the army medical corps.

The Civil War was also the first war to bring veterans' mental health issues to the attention of doctors. Jacob Mendez da Costa (1833–1900), a professor at Jefferson Medical College in Philadelphia, identified a disorder that he called the "irritable heart," an **anxiety** disorder that he observed in Civil War veterans, characterized by breathlessness, panicky feelings, and chest pains on mild exertion. It was sometimes called "soldier's heart" in World War I. Although da Costa's syndrome was not the same as what is now called *post-traumatic stress disorder* (PTSD), recent historical studies of Civil War veterans' health records indicate that many of these men also met contemporary criteria for PTSD. Those at greatest risk were men younger than 18 at the time of service and those who served in units with higher-than-average casualty rates. In addition, doctors and nurses who treated combat casualties developed PTSD even when they were not on the battlefield themselves. Walt Whitman (1819–1892), the American poet, served as a nurse in a military hospital in Washington, DC, between 1862 and 1865; his diary records his having symptoms of PTSD such as flashbacks, nightmares, **insomnia**, startle reactions, and nausea after his periods on duty.

Mental health issues in the military

Post-traumatic stress disorder

Post-traumatic stress disorder, or PTSD, was not formally introduced as a psychiatric diagnostic category until the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-III*) in 1980, although it has doubtless affected civilians as well as combat veterans for millennia. The earliest recorded case of it concerns an uninjured Athenian hoplite (citizen-soldier) who became blind from emotional **shock** after witnessing the death of a comrade during the Battle of Marathon in 490 B.C. It is helpful to keep in mind in this context that psychiatry itself is a relatively young medical specialty; Sigmund Freud was a boy of five at the outbreak of the Civil War in 1861.

The notion of evaluating soldiers in combat situations for psychiatric as well as physical symptoms originated in the British army on the Western Front during World War I (1914–1918) when infantrymen in the trenches began to develop what was then called *shell shock*—a combat **stress** reaction marked by indecision, disorientation, inability to set priorities, and a blank and unfocused expression colloquially known as the "thousand-yard stare," a sign of dissociation. During World War II (1939–1945), the condition was generally called *combat fatigue* or *traumatic war neurosis*, terms that are now obsolete. It was not until the Vietnam War that studies of combat veterans eventually produced the current definition of PTSD. The diagnosis was not applied to civilian survivors of traumatic incidents until the 1980s.

Demographics for PTSD for American veterans of different wars are difficult to estimate because of changing definitions of combat stress reactions as well as differences among branches of the service and the theaters in which they operated. The overall lifetime rate of PTSD for World War II veterans is estimated at 25%, with rates in the Army and Marine Corps higher than in the Navy, Coast Guard, or Air Force (called the Army Air Corps before 1947). For World War II veterans who had been prisoners of war, the rate of PTSD was three times higher (36%) for POW veterans of the Pacific Theater than for those taken prisoner in Europe (12%); traumatic memories persisted as long as 65 years after the experience of captivity. The lifetime rate for Vietnam veterans is estimated at 31% for men and 27% for women; for veterans of the Gulf War, from 9% to 24%; for veterans of Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF), 10% to 18%. For purposes of comparison, the lifetime rate of PTSD in the general population is 7% to 8%. Risk factors for PTSD in OIF/OEF veterans include lower service rank, single marital status, female gender, Hispanic ethnicity, longer deployment time, **traumatic brain injury**, family problems at home, prior history of childhood **trauma**, and lower level of education.

The VA established the National Center for PTSD in 1989 to perform research and education on the understanding, treatment, and prevention of PTSD. Although the Center does not provide direct clinical care for veterans with PTSD, it educates both military and civilian physicians about the disorder, maintains a research database called PILOTS (Published International Literature on Traumatic Stress), and has a website with numerous pages about various aspects of PTSD, ranging from self-assessment and

self-help to women's issues, post-deployment syndrome, and special programs for Native American, Hispanic, and African American veterans.

Gulf War syndrome

Gulf War syndrome (GWS) is a condition reported by some veterans of the 1991 Gulf War marked by chronic **fatigue**; headaches; memory problems; disturbed sleep; and digestive, skin, muscle, and joint disorders. GWS is a controversial diagnosis because of the wide variety of symptoms claimed as its characteristic features and because of the lack of a standardized definition of the syndrome. A report issued by the Institute of Medicine (IOM) in 2006 concluded, "Although veterans of the first Gulf War report significantly more symptoms of illness than soldiers of the same period who were not deployed, studies have found no cluster of symptoms that constitute a syndrome unique to Gulf War veterans." One reason given for the existence of a distinct syndrome was exposure to a combination of chemicals and contaminants never previously encountered in a war zone. These included bromide pills given to protect troops from the effects of nerve agents, depleted uranium munitions, and **anthrax** and botulinum vaccines. Another environmental hazard was toxic smoke from hundreds of burning oil wells.

About 700,000 American men and women served in the Gulf War in 1991; about 30% of them have registered with the database set up by the American Legion to track illnesses related to the war. Studies conducted by the Institute of Medicine and the National Academy of Sciences (NAS) in 2005 and 2006 surveyed 19,000 veterans of the Gulf War. Other medical reports by doctors in the field covered an additional 80,000 soldiers. What seems clear is that the medical symptoms of GWS cannot be explained as PTSD. While some veterans of the Gulf War did develop PTSD, a second IOM report in 2010 concluded that "the excess of unexplained medical symptoms reported by deployed Gulf war veterans cannot be reliably ascribed to any known psychiatric disorder." The medical symptoms are now generally described as multisystem illness, or MSI.

Post-deployment syndrome

Post-deployment syndrome (PDS) is sometimes used to describe a combination of PTSD, depression, **generalized anxiety disorder** (GAD), chronic **pain**, and traumatic brain injury (TBI) lasting longer than three to six months. It is a condition diagnosed primarily in veterans of the conflicts in Iraq and Afghanistan rather than earlier wars. Research into PDS was ongoing as of 2011, with a focus on finding effective treatments.

Women's issues

Women have served in frontline combat at least occasionally since the nineteenth century. According to diaries from the period and government records, about 750 women successfully disguised themselves as men and served in both Union and Confederate armies during the Civil War. Russian women served in combat in both World War I (the "Women's Battalion of Death" numbered about 2,000 soldiers in 1917) and World War II (about 800,000 women served as snipers, tank crew members, machine gunners, and pilots during the course of the war). Although American women generally served in support roles during earlier conflicts, as of 2011 they were the fastest-growing group of veterans. Women currently account for 11% of all OIF/OEF veterans.

The VA has identified four particular stressors for women in the military: combat missions, military sexual trauma or MST (defined as "any kind of unwanted sexual attention includ[ing] insulting sexual comments, unwanted sexual advances, or even sexual assault"), feeling alone or unsupported in newly formed military units, and concern about children or elderly parents at home. There is evidence that sexual harassment and assault are more common in wartime than in peacetime military duty. A study of MST during the Gulf War reported high rates of sexual assault (7%), physical sexual harassment (33%), and verbal sexual harassment (66%). In another study, 23% of female users of VA healthcare reported experiencing at least one sexual assault while in the military.

One reason that MST is so debilitating is that the military places a very high value on unit cohesion; thus, reporting sexual harassment or assault perpetrated by another member of the unit is considered taboo. Male victims of MST have a higher rate of PTSD (65%) than females (45%), partly because the male gender role causes many men to feel intense shame about their victimization, making them less likely to seek professional help.

Traumatic brain injury

Traumatic brain injury (TBI) refers to a type of closed-head injury resulting from a blow or jolt to the head; it can result from **whiplash** injuries as well as a motor vehicle accident, blast, or fall. TBIs can be evaluated as mild, moderate, or severe, depending on whether the person was knocked out and how long

WWW.BOOKBAZ.IR

they were unconscious. In a mild TBI, the person either does not lose consciousness at all or is unconscious for 30 minutes or less. In a moderate TBI, the person is unconscious for longer than 30 minutes but less than six hours. Unconsciousness lasting longer than six hours indicates a severe TBI.

One of the difficulties of diagnosing a TBI is that some of the emotional and cognitive symptoms overlap with those of PTSD. TBI symptoms may include trouble with concentration, acting without thinking, **memory loss**, difficulty translating thoughts into words, anger, anxiety, depression, or changes in personality. It is important to make sure that someone who has suffered a TBI together with (or instead of) PTSD receives the proper treatment. People with TBIs should not receive certain types of medications, including several classes of **antidepressant drugs**, which may aggravate some symptoms of the TBI, such as vertigo. Other drugs that should be avoided include those that may make the patient more susceptible to seizures (e.g., bupropion) or drugs that may cause confusion (e.g., **benzodiazepines**, lithium).

TBIs are of particular concern to current military and VA doctors because the rate of such injuries is higher (22%) in veterans of Iraq and Afghanistan than in Vietnam veterans (12%). The major causes of TBIs in recent veterans are blasts, motor vehicle accidents, and gunshot **wounds**. Because many veterans with TBIs have coexisting PTSD or substance abuse disorders, they typically take longer than civilians to recover from these head injuries. Veterans with TBIs are also almost twice as likely to attempt **suicide** than veterans who did not suffer such injuries.

Suicide

Statistics kept since World War I indicate that American combat veterans are twice as likely to die from suicide than male adults in the general population. In 2011, the VA reported that there were, on average, 950 suicide attempts each month among veterans receiving some type of VA treatment. Seven percent of these attempts were successful; 11% of attempters were expected to try again within the next nine months. The number of veterans' suicides between 2005 and 2009—1,100—exceeded that of the number of military personnel killed in Afghanistan since 2001.

Access to health care is an important factor in suicide prevention among veterans. Only 8 million of the 23 million veterans in the United States are currently registered with the Department of Veteran Affairs. The data indicate that for veterans between the ages of 18 and 29, the suicide rate is lower for those receiving VA health care than for those who do not seek help. The VA's suicide hotline (800-273-8255, press 1) receives about 10,000 calls per month from current and former service members. One major area of concern is the rising risk of suicide among OIF and OEF veterans. In 2009, there were 1,621 suicide attempts by men and 247 by women veterans of these conflicts, with 94 men and 4 women dying. As in the civilian population, women veterans attempt suicide more often than men, but men are more often successful, mostly because they are more likely to use firearms.

In 2011, the NIMH and the U.S. Army announced the beginning of a suicide-prevention study known as the Army Study to Assess Risk and Resilience in Servicemembers, or the Army STARRS program. The largest study ever conducted to assess mental health issues among military personnel, the Army STARRS program will run through 2014. The study has four separate components: an investigation of historical data, evaluation of new soldiers, an All-Army study, and a health outcomes investigation. Participation is voluntary.

Military mental health services

Statistics indicate that almost half of the 1 million service personnel deployed to Iraq or Afghanistan between 2002 and 2009 sought some form of health care from the VA. Of that fraction, 48% (about 221,000 persons) were diagnosed with mental health issues, including depression and **anxiety disorders** other than PTSD. Treatment is available for veterans at all VA hospitals, Vet Centers, and community clinics working in partnership with the VA.

As of 2011, there were over 200 specialized treatment programs for PTSD within the VA system, covering veterans from World War II and all later conflicts. Several types of therapy are offered, including individualized assessment and **psychotherapy**, medications, **family therapy**, and **group therapy** (including **anger management**, combat support, and groups for veterans of specific conflicts). Programs range from intensive residential or inpatient treatment programs lasting 28–90 days in day clinics, walk-in community-based clinics, and Vet Center group therapy programs staffed by veterans. A special 60-day residential PTSD program for female veterans, the National Women's Trauma Recovery Program (WTRP), is run by the center in Menlo Park, California.

The National Center for PTSD also has a menu of self-help options on its website, ranging from mindfulness practice and recommendations for a

KEY TERMS

Combat stress reaction—A general term for mental health symptoms that include depression, fatigue, dissociative symptoms, difficulty focusing, and irritability. It is not identical to PTSD but may be a precursor of it. The condition was sometimes referred to as combat fatigue in World War II.

Dissociation—A psychological mechanism in which the mind splits off certain aspects of a traumatic event from conscious awareness. Dissociation can affect the patient's memory, sense of reality, and sense of identity. Dissociative symptoms are commonly experienced by persons with PTSD.

Post-deployment syndrome (PDS)—A term developed to describe a constellation of mental disorders found in veterans of the conflicts in Iraq and Afghanistan. PDS includes PTSD, generalized anxiety disorder, major depression, chronic pain, and traumatic brain injury.

Resilience—In psychiatry, the ability of a person to respond positively to, or bounce back from, trauma or hardship. Resilience is considered a process of interaction between the person and his or her environment rather than a one-time action.

Syndrome—A group of signs or symptoms that occur together and characterize or define a particular disease or disorder.

Triage—A process for determining the order and priority of emergency treatment for injured people (civilians or military personnel); the order and priority of emergency transport; and/or the injured person's transport destination.

healthy lifestyle to an iPhone app called PTSD Coach that helps users recognize and manage symptoms of PTSD.

According to the VA, there are a number of reasons why veterans are often reluctant to seek help for mental health issues:

- They do not want to be seen as weak.
- They are concerned about privacy.
- They would rather rely on family and friends.
- They are concerned about possible side effects of medications.
- They do not think treatment will help them.
- They have problems with access to treatment, in terms of cost or geographical location.
- If they are still actively serving, they are concerned about losing future promotions.

As of 2011, there were 322 clinical trials under way in the general area of mental health care for veterans. Studies include investigations of various types of psychotherapy and other interventions for PTSD, telephone case monitoring and outreach for World War II veterans as well as younger veterans, Internet- and smartphone-based psychotherapy for rural veterans, suicide-prevention programs, special studies of female veterans, trials of various medications for Gulf War veterans with multisystem illness, and investigations of programs for post-deployment reintegration into civilian life.

function dependent on the mineral. In other cases, the convention may be to define an abnormally low mineral concentration as a level lower than that found in a specific healthy population.

The mineral nutrients are defined as all inorganic substances that are required for life. As far as human **nutrition** is concerned, the inorganic nutrients include water, **sodium**, potassium, chloride, **calcium**, phosphate, sulfate, magnesium, iron, copper, zinc, manganese, iodine, selenium, and molybdenum. Although these substances are all elements, they are never consumed in that form in the diet. Instead, they are consumed in the form of compounds, such as sulfates and iodides.

There is some evidence that other inorganic nutrients, such as chromium and boron, play a part in human health, but their role is not well established. Fluoride has been proven to increase the strength of bones and teeth, but there is little or no reason to believe that it is needed for human life.

The mineral content of the body may be measured by testing samples of blood plasma, red blood cells, or urine. In the case of calcium and phosphate deficiency, the diagnosis may also involve taking x rays of the skeleton. In the case of iodine deficiency, the diagnosis may include examining the patient's neck with the eyes and hands. In the case of iron deficiency, the diagnosis may include the performance of a stair-stepping test by the patient. Since all minerals serve strikingly different functions in the body, tests for the corresponding deficiency are markedly different from each other.

WWW.BOOKBAZ.IR

Description

Laboratory studies with animals have revealed that severe deficiencies in any one of the inorganic nutrients can result in very specific symptoms, and finally in death, due to the failure of functions associated with that nutrient. In humans, deficiency in one nutrient may occur less often than deficiency in several nutrients. A patient suffering from **malnutrition** tends to be deficient in a variety of nutrients. In the United States, malnutrition is most often found among severe alcoholics. In part, this is because alcohol consumption may supply half of the energy requirement, resulting in a mineral and vitamin intake of half the expected level. Deficiencies in one nutrient do occur, for example, in human populations living in iodine–poor regions of the world, and in iron deficient persons who lose excess iron by abnormal bleeding.

Inorganic nutrients have a great variety of functions in the body. Water, sodium, and potassium deficiencies are most closely associated with abnormal nerve action and cardiac **arrhythmias**. Deficiencies in these nutrients tend to result not from a lack of content in the diet, but from excessive losses due to severe **diarrhea** and other causes. Iodine deficiency is a global **public health** problem. It occurs in parts of the world with iodine-deficient soils, and results in **goiter**, which involves a relatively harmless swelling of the neck, and cretinism, a severe birth defect. The only use of iodine in the body is for making thyroid hormone. However, since thyroid hormone has a variety of roles in development of the embryo, iodine deficiency during **pregnancy** results in a number of **birth defects**.

Calcium deficiency due to lack of dietary calcium occurs only rarely. However, calcium deficiency due to **vitamin D** deficiency can be found among certain populations. Vitamin D is required for the efficient absorption of calcium from the diet, and hence vitamin D deficiency in growing infants and children can result in calcium deficiency.

Dietary phosphate deficiency is rare because phosphate is plentiful in plant and animal foods, but also because phosphate is efficiently absorbed from the diet into the body. Iron deficiency causes anemia (lack of red blood cells), which results in tiredness and **shortness of breath**.

Dietary deficiencies in the remaining inorganic nutrients tend to be rare. Magnesium deficiency is uncommon, but when it occurs it tends to occur in chronic alcoholics, in persons taking diuretic drugs, and in those suffering from severe and prolonged diarrhea. Magnesium deficiency tends to occur with the same conditions that provoke deficiencies in sodium and potassium. Zinc deficiency is rare, but it has been found in impoverished populations in the Middle East, who rely on unleavened whole wheat bread as a major food source. Copper deficiency is also rare, but dramatic and health-threatening changes in copper metabolism occur in two genetic diseases, Wilson's disease and Menkes' disease.

Selenium deficiency may occur in regions of the world where soils are poor in selenium. Low-selenium soils can produce foods that are also low in selenium. Premature infants may also be at risk for selenium deficiency. Manganese deficiency is very rare. Experimental studies with humans fed a manganese deficient diet have revealed that the deficiency produces a scaly, red rash on the skin of the upper torso. Molybdenum deficiency has probably never occurred, but indirect evidence suggests that if molybdenum deficiency could occur, it would result in intellectual disabilities (ID) and death.

Causes and symptoms

Sodium deficiency (**hyponatremia**) and water deficiency are the most serious and widespread deficiencies in the world. These deficiencies tend to arise from excessive losses from the body, as during prolonged and severe diarrhea or **vomiting**. Diarrheal diseases are a major world health problem, and are responsible for about a quarter of the 10 million infant deaths that occur each year. Nearly all of these deaths occur in impoverished parts of Africa and Asia, where they result from contamination of the water supply by animal and human feces.

The main concern in treating diarrheal diseases is **dehydration**, that is, the losses of sodium and water which deplete the fluids of the circulatory system (the heart, veins, arteries, and capillaries). Severe losses of the fluids of the circulatory system result in **shock**. Shock nearly always occurs when dehydration is severe enough to produce a 10% reduction in body weight. Shock, which is defined as inadequate supply of blood to the various tissues of the body, results in a lack of oxygen to all cells of the body. Although diarrheal fluids contain a number of electrolytes, the main concern in avoiding shock is the replacement of sodium and water.

Sodium deficiency and potassium deficiency also frequently result during treatment with drugs called **diuretics**. Diuretics cause loss of sodium from the body. These drugs are used to treat high blood pressure (**hypertension**), where the resulting decline in blood pressure reduces the risk for cardiovascular disease. However, diuretics can lead to sodium deficiency,

resulting in low plasma sodium levels. A side effect of some diuretics is excessive loss of potassium, and low plasma potassium (**hypokalemia**) may result.

Iodine deficiency tends to occur in regions of the world where the soil is poor in iodine. Where soil used in agriculture is poor in iodine, foods grown in the soil will also be low in iodine. An iodine intake of 0.10–0.15 mg/day is considered to be nutritionally adequate, while iodine deficiency occurs at levels of less than 0.05 mg/day. Goiter, an enlargement of the thyroid gland (located in the neck), results from iodine deficiency. Goiter continues to be a problem in eastern Europe, parts of India and South America, and in Southeast Asia. Goiter has been eradicated in the United States because of the fortification of foods with iodine. Iodine deficiency during pregnancy results in cretinism in the newborn. Cretinism involves ID, a large tongue, and sometimes deafness, muteness, and lameness.

Iron deficiency occurs due to periods of dietary deficiency, rapid growth, and excessive loss of the body's iron. Human milk and cow milk both contains low levels of iron. Infants are at risk for acquiring iron deficiency because their rapid rate of growth depends on a corresponding increased supply of dietary iron, for use in making blood and muscles. Human milk is a better source of iron than cow milk, since about half of the iron in human breast milk is absorbed by the infant's digestive tract. In contrast, only 10% of the iron in cow milk is absorbed by the infant. Surveys of lower-income families in the United States have revealed that about six percent of infants are anemic indicating a deficiency of iron in their **diets**. Blood loss that occurs with menstruation in women, as well as with a variety of causes of intestinal bleeding is a major cause of iron deficiency. The symptoms of iron deficiency are generally limited to anemia, and the resulting tiredness, weakness, and a reduced ability to perform physical work.

Calcium and phosphate are closely related nutrients. About 99% of the calcium and 85% of the phosphate in the body occur in the skeleton, where they exist as crystals of solid calcium phosphate. Both of these nutrients occur in a great variety of foods. Milk, eggs, and green, leafy vegetables are rich in calcium and phosphate. Whole cow milk, for example, contains about 1.2 g calcium and 0.95 g phosphorus per kg of food. Broccoli contains 1.0 g calcium and 0.67 g phosphorus per kg food. Eggs supply about one third of the calcium and phosphate of the overall population of the United States. Dietary deficiencies in calcium (**hypocalcemia**) or phosphate are extremely rare throughout the world. Vitamin D deficiency can be found among young infants, the elderly, and others who may be shielded from sunshine for prolonged periods of time. Vitamin D deficiency impairs the absorption of calcium from the diet, and in this way can provoke calcium deficiency even when the diet contains adequate calcium.

Zinc deficiency has been found among peasant populations in rural areas of the Middle East. Unleavened whole wheat bread can account for 75% of the energy intake in these areas. This diet, which does not contain meat, does contain zinc, but it also contains phytic acid at a level of about three grams per day. Phytic acid, which occurs naturally in wheat, inhibits zinc absorption. The yeast used to leaven bread produces enzymes that inactivate the phytic acid. Unleavened bread does not contain yeast; therefore, it contains intact phytic acid. The symptoms of zinc deficiency include lack of sexual maturation, lack of pubic hair, and small stature. The amount of phytic acid in a typical American diet cannot provoke zinc deficiency.

Zinc deficiency is relatively uncommon in the United States, but it may occur in adults with **alcoholism** or intestinal malabsorption problems. Low plasma zinc has been found in patients with alcoholic **cirrhosis**, Crohn's disease, and **celiac disease**. Experimental studies with humans have shown that the signs of zinc deficiency are detectable after two to five weeks of consumption of the zinc–free diet. The signs include a rash and diarrhea. The rash occurs on the face, groin, hands, and feet. These symptoms can easily be reversed by administering zinc. An emerging concern is that increased calcium intake can interfere with zinc absorption or retention. Hence, there is some interest in the question as to whether persons taking calcium to prevent **osteoporosis** should also take zinc supplements.

Severe alterations in copper metabolism occur in two genetic diseases, Wilson's disease and Menkes' disease. Both of these diseases are rare and occur in about one in 100,000 births. Both diseases involve mutations in copper transport proteins, that is, in special channels that allow the passage of copper ions through cell membranes. Menkes' disease is a genetic disease involving **intellectual disability** and death before the age of three years. The disease also results in steely or kinky hair. The hair is tangled, grayish, and easily broken. Menkes' disease involves a decrease in copper levels in serum, the liver, and brain, and increases in copper in cells of the intestines and kidney.

Selenium deficiency may occur in premature infants, since this population naturally tends to have

WWW.BOOKBAZ.IR

low levels of plasma selenium. Full term infants have plasma selenium levels of about 0.001–0.002 mM, while premature infants may have levels about one third this amount. Whether these lower levels result in adverse consequences is not clear. Selenium deficiency occurs in regions of the world containing low–selenium soils. These regions include Keshan Province in China, New Zealand, and Finland. In Keshan Province, a disease (Keshan disease) occurs which results in deterioration of regions of the heart and the development of fibers in these regions. Keshan disease, which may be fatal, is thought to result from a combination of selenium deficiency and a virus.

Diagnosis

The diagnosis of deficiencies in water, sodium, potassium, iron, calcium, and phosphate involves chemical testing of the blood plasma, urine, and red blood cells.

Iodine deficiency can be diagnosed by measuring the concentration of iodine in the urine. A urinary level greater than 0.05 mg iodine per gram creatinine means adequate iodine status. Levels under 0.025 mg iodine/g creatinine indicate a serious risk.

Normal blood serum magnesium levels are 1.2–2.0 mM. Magnesium deficiency results in hypomagnesemia, which is defined as serum magnesium levels below 0.8 mM. Magnesium levels below 0.5 mM provoke a decline in serum calcium levels. Hypomagnesemia can also result in low serum potassium. Some of the symptoms of hypomagnesemia, which include twitching and convulsions, actually result from the hypocalcemia. Other symptoms of hypomagnesemia, such as cardiac arrhythmias, result from low potassium levels.

There is no reliable test for zinc deficiency. When humans eat diets containing normal levels of zinc (16 mg/day), the level of urinary zinc is about 0.45 mg/day, while humans consuming low–zinc diets (0.3 mg/day) may have urinary levels of about 0.150 mg/day. Plasma zinc levels tend to be maintained during a dietary deficiency in zinc. Plasma and urinary zinc levels can be influenced by a variety of factors, and for this reason cannot provide a clear picture of zinc status.

Selenium deficiency may be diagnosed by measuring the selenium in plasma or red blood cells, where the normal values are 70 ng/mL and 90 ng/mL, respectively. There is also some interest in measuring the activity of an enzyme in blood platelets, in order to assess selenium status. This enzyme is glutathione peroxidase. Platelets are small cells of the bloodstream which are used mainly to allow the clotting of blood after an injury.

Treatment

The treatment of deficiencies in sodium, potassium, calcium, phosphate, and iron usually involves intravenous injections of the deficient mineral.

Iodine deficiency can be easily prevented and treated by fortifying foods with iodine. Table salt is fortified with 100 mg potassium iodide per kg sodium chloride. Goiter was once common in the United States in areas from Washington State to the Great Lakes region, but this problem has been eliminated by the use of iodized salt. Public health programs in impoverished countries have involved injections of synthetic oils containing iodine. Goiter is reversible but, cretinism is not.

Magnesium deficiency can be treated with a magnesium-rich diet. If magnesium deficiency is due to a prolonged period of depletion, treatment may include injections of magnesium sulfate (2.0 mL of 50% $MgSO_4$). Where magnesium deficiency is severe enough to provoke convulsions, magnesium needs to be administered by injections or infusions. For infusion, 500 mL of a 1% solution (1 gram/100 mL) of magnesium sulfate is gradually introduced into a vein over the course of about five hours.

Zinc deficiency and copper deficiency are quite rare, but when they are detected or suspected, they can be treated by consuming zinc or copper, on a daily basis, at levels defined by the RDA.

Selenium deficiency in adults can be treated by eating 100 mg selenium per day for a week, where the selenium is supplied as selenomethionine. The incidence of Keshan disease in China has been reduced by supplementing children's diets with 1.0 mg sodium selenite per week.

Prognosis

In iodine deficiency, the prognosis for treating goiter is excellent; however, cretinism cannot be reversed. The effects of iron deficiency are not life–threatening and can be easily treated. The prognosis for treating magnesium deficiency is excellent. The symptoms may be relieved promptly or, at most, within two days of starting treatment. In cases of zinc deficiency in Iran and other parts of the Middle East, supplementation of the diets of affected young adults with zinc has been found to provoke the growth of pubic hair and enlargement of genitalia to a normal size within a few months.

KEY TERMS

Recommended Dietary Allowance—The Recommended Dietary Allowances (RDAs) are quantities of nutrients that are required each day to maintain human health. RDAs are established by the Food and Nutrition Board of the National Academy of Sciences and may be revised every few years. A separate RDA value exists for each nutrient.

Prevention

In a healthy population, all mineral deficiencies can be prevented by the consumption of inorganic nutrients at levels defined by the Recommended Dietary Allowances (RDA). Where a balanced diet is not available, government programs for treating individuals, or for fortifying the food supply, may be used. Government sponsored programs for the prevention of iron deficiency and iodine deficiency are widespread throughout the world. Selenium treatment programs have been used in parts of the world where selenium deficiency exists. Attention to potassium status, and to the prevention of potassium deficiency, is an issue mainly in patients taking diuretic drugs. In many cases of mineral deficiency, the deficiency occurs because of disease, and individual medical attention, rather than preventative measures, is used. The prevention of calcium deficiency is generally not an issue or concern, however calcium supplements are widely used with the hope of preventing osteoporosis. The prevention of deficiencies in magnesium, zinc, copper, manganese, or molybdenum are not major health issues in the United States. Ensuring an adequate intake of these minerals, by eating a balanced diet or by taking mineral supplements, is the best way to prevent deficiencies.

Mineral excess *see* **Mineral toxicity**

Mineral toxicity

Definition

The term *mineral toxicity* means a condition in which the concentration in the body of any one of a variety of **minerals** is abnormally high, and in which there is an adverse effect on health.

Description

In general, mineral toxicity results when there is an accidental consumption of too much of any mineral, as with drinking ocean water (**sodium** toxicity) or with overexposure to industrial pollutants, household chemicals, or certain drugs. Mineral toxicity may also apply to toxicity that can be the result of certain diseases or injuries. For example, **hemochromatosis** leads to iron toxicity; Wilson's disease results in copper toxicity; severe **trauma** can lead to **hyperkalemia** (potassium toxicity).

The mineral nutrients are defined as all the inorganic substances that are required for life. As far as human **nutrition** is concerned, the inorganic nutrients include water, sodium, potassium, chloride, **calcium**, phosphate, sulfate, magnesium, iron, copper, zinc, manganese, iodine, selenium, and molybdenum.

The mineral content of the body may be measured by testing samples of blood plasma, red blood cells, and urine.

WWW.BOOKBAZ.IR

Causes and symptoms

An increase in the concentrations of sodium in the bloodstream can be toxic. The normal concentration of sodium in blood plasma is 136–145 mM, while levels over 152 mM can result in seizures and death. Increased plasma sodium, which is called **hypernatremia**, causes various cells of the body, including those of the brain, to shrink. Shrinkage of brain cells results in confusion, **coma**, **paralysis** of the lung muscles, and death. Death has occurred in situations in which table salt (sodium chloride) was accidently used, instead of sugar, for feeding infants. Death due to sodium toxicity has also resulted when baking soda (sodium bicarbonate) was used during attempted therapy of excessive **diarrhea** or **vomiting**. Although a variety of processed foods contain high levels of sodium chloride, the levels used are not enough to result in sodium toxicity.

The normal level of potassium in the bloodstream is in the range of 3.5–5.0 mM, while levels of 6.3–8.0 mM (severe hyperkalemia) result in cardiac **arrhythmias** or even death due to cardiac arrest. Potassium is potentially quite toxic; however toxicity or death due to potassium **poisoning** is usually prevented because of the vomiting reflex. Consumption of food results in mild increases in the concentration of potassium in the bloodstream, but levels of potassium do not become toxic because of the uptake of potassium by various cells of the body, as well as by the action of the kidneys transferring the potassium ions from the blood to the urine. The body's regulatory mechanisms can easily be overwhelmed, however, when potassium chloride is injected intravenously, as high doses of injected potassium can easily result in death.

Iodine toxicity can result from an intake of 2.0 mg of iodide per day. Ttoxicity results in impairment of the creation of thyroid hormone, resulting in lower levels of thyroid hormone in the bloodstream. The thyroid gland enlarges, as a consequence, and a **goiter** develops. This enlargement is also called **hyperthyroidism**. Goiter is usually caused by iodine deficiency. In addition to goiter, iodine toxicity produces **ulcers** on the skin. This condition has been called kelp acne, because of its association with eating kelp, an ocean plant, which contains high levels of iodine. Iodine toxicity occurs in Japan, where large amounts of seaweed are consumed.

Iron toxicity is not uncommon, due to the wide availability of iron pills. A lethal dose of iron is in the range of 200–250 mg iron/kg body weight. Hence, a child who accidently eats 20 or more iron tablets may die as a result of iron toxicity. Within six hours of ingestion, iron toxicity can result in vomiting, diarrhea, abdominal **pain**, seizures, and possibly coma. A latent period, during which symptoms appear to improve, may occur, but that period is followed by **shock**, low blood glucose, liver damage, convulsions, and death, occurring 12–48 hours after toxic levels of iron are ingested.

Nitrite poisoning should be considered along with iron toxicity, since nitrite produces its toxic effect by reacting with the iron component of hemoglobin. Hemoglobin is an iron-containing protein found in red blood cells. This protein is responsible for the transport of nearly all of the oxygen, acquired from the lungs, to various tissues and organs of the body. Hemoglobin accounts for the red color of red blood cells. A very small fraction of hemoglobin spontaneously oxidizes per day, producing a protein of a slightly different structure, called methemoglobin. Normally, the amount of methemoglobin constitutes less than one percent of total hemoglobin. Methemoglobin can accumulate in the blood as a result of nitrite poisoning. Infants are especially susceptible to poisoning by nitrite.

Nitrate, which is naturally present in green leafy vegetables and in the water supply is rapidly converted to nitrite by naturally occurring bacteria residing on our tongue, as well as in the intestines, and then absorbed into the bloodstream. The amount of nitrate that is supplied by leafy vegetables and in drinking water is generally about 100–170 mg/day. The amount of nitrite supplied by a typical diet is much less, that is, than 0.1 mg nitrite/day. Poisoning by nitrite, or nitrate after its conversion to nitrite, results in the inability of hemoglobin to carry oxygen throughout the body. This condition is manifested by the blue color of skin. Adverse symptoms occur when over 30% of hemoglobin has been converted to methemoglobin, and these symptoms include cardiac arrhythmias, **headache**, **nausea and vomiting**, and in severe cases, seizures.

Calcium and phosphate are closely related nutrients. Calcium toxicity is rare, but overconsumption of calcium supplements may lead to deposits of calcium phosphate in the soft tissues of the body. Phosphate toxicity can occur with overuse of **laxatives** or **enemas** that contain phosphate. Severe phosphate toxicity can result in **hypocalcemia**, and in various symptoms resulting from low plasma calcium levels. Moderate phosphate toxicity, occurring over a period of months, can result in the deposit of calcium phosphate crystals in various tissues of the body.

KEY TERMS

Recommended Dietary Allowance—The Recommended Dietary Allowances (RDAs) are quantities of nutrients that are required each day to maintain human health. RDAs are established by the Food and Nutrition Board of the National Academy of Sciences and may be revised every few years. A separate RDA value exists for each nutrient.

Zinc toxicity is rare, but it can occur in metal workers who are exposed to fumes containing zinc. Excessive dietary supplements of zinc can result in nausea, vomiting, and diarrhea. Chronic intake of excessive zinc supplements can result in copper deficiency, as zinc inhibits the absorption of copper.

Severe alterations in copper metabolism occur in two genetic diseases, Wilson's disease and Menkes' disease. Both of these diseases are rare and occur in about one in 100,000 births. Both diseases involve mutations in the proteins that transport copper, that is, in special channels that allow the passage of copper ions through cell membranes. Wilson's disease tends to occur in teenagers and in young adults, and then remain for the lifetime. Copper accumulates in the liver, kidney, and brain, resulting in damage to the liver and nervous system. Wilson's disease can be successfully controlled by lifelong treatment with d–penicillamine. Treatment also involves avoiding foods that are high in copper, such as liver, nuts, chocolate, and mollusks. After an initial period of treatment with penicillamine, Wilson's disease may be treated with zinc (150 mg oral Zn/day). The zinc inhibits the absorption of dietary copper.

Selenium toxicity occurs in regions of the world, including some parts of China, where soils contain high levels of selenium. A daily intake of 0.75–5.0 mg selenium may occur in these regions, due to the presence of selenium in foods and water. Early signs of selenium toxicity include nausea, weakness, and diarrhea. With continued intake of selenium, changes in fingernails and hair loss results, and damage to the nervous system occurs. The breath may acquire a garlic odor, as a result of the increased production of dimethylselenide in the body, and its release via the lungs.

Manganese toxicity occurs in miners in manganese mines, where men breath air containing dust bearing manganese at a concentration of 5–250 mg/cubic meter. Manganese toxicity in miners has been documented in Chile, India, Japan, Mexico, and elsewhere. Symptoms of manganese poisoning typically occur within several months or years of exposure. These symptoms include a mental disorder resembling **schizophrenia**, as well as hyperirritability, violent acts, **hallucinations**, and difficulty in walking.

Diagnosis

The initial diagnosis of mineral toxicity involves questioning the patient in order to determine any unusual aspects of the diet, unusual intake of drugs and chemicals, and possible occupational exposure. Diagnosis of mineral toxicities also involves measuring the metal concentration in the plasma or urine. Concentrations that are above the normal range can confirm the initial, suspected diagnosis.

Treatment

Iron toxicity is treated by efforts to remove remaining iron from the stomach, by use of a solution of 5% sodium bicarbonate. Where plasma iron levels are above 0.35 mg/dL, the patient is treated with deferoxamine. Treatment of manganese toxicity involves removal of the patient from the high manganese environment, as well as lifelong doses of the drug L–dopa. The treatment is only partially successful. Treatment of nitrite or nitrate toxicity involves inhalation of 100% oxygen for several hours. If oxygen treatment is not effective, then methylene blue may be injected, as a 1.0% solution, in a dose of 1.0 mg methylene blue/kg body weight.

Prognosis

The prognosis for treating toxicity due to sodium, potassium, calcium, and phosphate is usually excellent. Toxicity due to the deposit of calcium phosphate crystals is not usually reversible. The prognosis for treating iodine toxicity is excellent. For any mineral overdose that causes coma or seizures, the prognosis for recovery is often poor, and death results in a small fraction of patients. For any mineral toxicity that causes nerve damage, the prognosis is often fair to poor.

WWW.BOOKBAZ.IR

Prevention

When mineral toxicity results from the excessive consumption of mineral supplements, toxicity can be prevented by not using supplements. In the case of manganese, toxicity can be prevented by avoiding work in manganese mines. In the case of iodine, toxicity can be prevented by avoiding overconsumption of seaweed or kelp. In the case of selenium toxicity that arises due to high-selenium soils, toxicity can be prevented by relying on food and water acquired from a low–selenium region.

Minerals

Definition

Minerals are inorganic elements that originate in the earth and cannot be made in the body. They play important roles in various bodily functions and are necessary to sustain life and maintain optimal health and thus are essential nutrients. Most of the minerals in the human diet come directly from plants and water or indirectly from animal foods. However, the mineral content of water and plant foods varies geographically because of variations in the mineral content of soil from region to region.

Purpose

Minerals provide structure to bones and teeth and participate in energy production, the building of protein, blood formation, and several other metabolic processes.

Description

The amount of minerals present in the body, and their metabolic roles, varies considerably. Minerals are categorized into major and trace minerals, depending on the amount needed per day. Major minerals are those that are required in the amounts of 100 mg (milligrams) or more, while trace minerals are required in amounts less than 100 mg per day. The terms *major* and *trace*, however, do not reflect the importance of a mineral in maintaining health, as a deficiency of either can be harmful.

Major minerals

The major minerals present in the body include **sodium**, potassium, chloride, **calcium**, magnesium, phosphorus, and sulfur.

The fluid balance in the body, vital for all life processes, is maintained largely by sodium, potassium, and chloride. Fluid balance is regulated by charged sodium and chloride ions in the extracellular fluid (outside the cell) and potassium in the intracellular fluid (inside the cell), and by some other electrolytes across cell membranes. Tight control is critical for normal muscle contraction, nerve impulse transmission, heart function, and blood pressure. Sodium plays an important role in the absorption of other nutrients, such as glucose, amino acids, and water. Chloride is a component of hydrochloric acid, an important part of gastric juice (an acidic liquid secreted by glands in the stomach lining) and aids in food digestion. Potassium and sodium act as cofactors for certain enzymes.

Calcium, magnesium, and phosphorus are known for their structural roles, as they are essential for the development and maintenance of bones and teeth. They are also needed for maintaining cell membranes and connective tissue. Several enzymes, hormones, and proteins that regulate energy and fat metabolism require calcium, magnesium and/or phosphorus to become active. Calcium also aids in blood clotting. Sulfur is a key component of various proteins and **vitamins** and participates in drug-detoxifying pathways in the body.

Trace minerals

Trace minerals are present (and required) in very small amounts in the body. An understanding of the important roles and requirements of trace minerals in the human body is fairly recent, and research is still ongoing. The most important trace minerals are iron, zinc, copper, chromium, fluoride, iodine, selenium, manganese, and molybdenum. Some others, such as arsenic, boron, cobalt, nickel, silicon, and vanadium, are recognized as essential for some animals, while others, such as barium, bromine, cadmium, gold, silver, and aluminum, are found in the body, though little is known about their role in health.

Trace minerals have specific biological functions. They are essential in the absorption and utilization of many nutrients and aid enzymes and hormones in activities that are vital to life. Iron plays a major role in oxygen transport and storage and is a component of hemoglobin in red blood cells and myoglobin in muscle cells. Cellular energy production requires many trace minerals, including iron, copper, and zinc, which act as enzyme cofactors in the synthesis of many proteins, hormones, neurotransmitters, and genetic material.

Iron and zinc support immune function, while chromium and zinc aid insulin action. Zinc is also essential for many other bodily functions, such as growth, development of sexual organs, and reproduction. Zinc, copper and selenium prevent oxidative damage to cells. Fluoride stabilizes bone mineral and hardens tooth enamel, thus increasing resistance to **tooth decay**. Iodine is essential for normal thyroid function, which is critical for many aspects of growth and development, particularly brain development. Thus, trace minerals contribute to physical growth and mental development.

Mineral bioavailability

The bioavailability of a nutrient refers to how effectively the nutrient can be absorbed and used by the body. Mineral bioavailability depends on several factors. Higher absorption occurs among individuals who are deficient in a mineral, while some elements in the diet (e.g., oxalic acid or oxalate in spinach) can decrease mineral availability by chemically binding to the mineral. In addition, excess intake of one mineral can influence the absorption and metabolism of other minerals. For example, the presence of a large amount of zinc in the diet decreases the absorption of iron and copper. On the other hand, the presence of vitamins in a meal enhances the absorption of minerals in the meal. For example, vitamin C improves iron absorption, and **vitamin D** aids in the absorption of calcium, phosphorous, and magnesium.

In general, minerals from animal sources are absorbed better than those from plant sources as minerals are present in forms that are readily absorbed and binders that inhibit absorption, such as phytates, are absent. Vegans (those who restrict their **diets** to plant foods) need to be aware of the factors affecting mineral bioavailability. Careful meal planning is necessary to include foods rich in minerals and absorption-enhancing factors.

Recommended intake

It is generally recommended that people eat a well-balanced diet to meet their mineral requirements, while avoiding deficiencies and chemical excesses or imbalances. However, supplements may be useful to meet dietary requirements for some minerals when dietary patterns fall short of Recommended Daily Allowances(RDAs) or Adequate Intakes(AIs) for normal healthy people.

The Food and **Nutrition** Board recommends that supplements or fortified foods be used to obtain desirable amounts of some nutrients, such as calcium and iron. The recommendations for calcium are higher than the average intake in the United States. Women, who generally consume lower energy diets than men, and individuals who do not consume dairy products can particularly benefit from calcium supplements. Because of the increased need for iron in women of childbearing age, as well as the many negative consequences of iron-deficiency anemia, iron supplementation is recommended for vulnerable groups in the United States, as well as in developing countries.

Precautions

Although severe deficiencies of better-understood trace minerals are easy to recognize, diagnosis is difficult for less-understood minerals and for mild deficiencies. Even mild deficiencies of trace minerals however, can result in poor growth and development in children.

Iron deficiency is the most common nutrient deficiency worldwide, including in the United States. Iron-deficiency anemia affects hundreds of millions of people, with highest prevalence in developing countries. Infants, young children, adolescents, and pregnant and lactating women are especially vulnerable due to their high demand for iron. Menstruating women are also vulnerable due to blood loss. Vegetarians are

WWW.BOOKBAZ.IR

another vulnerable group, as iron from plant foods is less bioavailable than that from animal sources.

Zinc deficiency, marked by severe growth retardation and arrested sexual development, was first reported in children and adolescent boys in Egypt, Iran, and Turkey. Diets in Middle Eastern countries are typically high in fiber and phytates, which inhibit zinc absorption. Mild zinc deficiency has been found in vulnerable groups in the United States. Copper deficiency is rare, but can be caused by excess zinc from supplementation.

Deficiencies of fluoride, iodine, and selenium mainly occur due to a low mineral content in either the water or soil in some areas of the world. Fluoride deficiency is marked by a high prevalence of dental caries and is common in geographic regions with low water-fluoride concentration, which has led to the fluoridation of water in the United States and many other parts of the world. **Goiter** and cretinism (a condition in which body growth and mental development are stunted) have been eliminated by iodization of salt in the United States, but still occur in parts of the world where salt manufacture and distribution are not regulated. Selenium deficiency due to low levels of the mineral in soil is found in northeast China, and it has been associated with Keshan disease, a heart disorder prevalent among people of that area.

Dietary deficiency is unlikely for most major minerals, except in starving people or those with **protein-energy malnutrition** in developing countries, or people on poor diets for an extended period, such as those suffering from **alcoholism**, anorexia, or bulimia. Most people in the world consume a lot of salt, and it is recommended that they moderate their intake to prevent chronic diseases (high salt intake has been associated with an increased risk of death from **stroke** and cardiovascular disease). However, certain conditions, such as severe or prolonged **vomiting** or **diarrhea**, the use of **diuretics**, and some forms of **kidney disease**, lead to an increased loss of minerals, particularly sodium, chloride, potassium, and magnesium. Calcium intakes tend to be lower in women and vegans who do not consume dairy products. Elderly people with suboptimal diets are also at risk of mineral deficiencies because of decreased absorption and increased excretion of minerals in the urine.

Toxicity from excessive dietary intake of major minerals rarely occurs in healthy individuals. Kidneys that are functioning normally can regulate mineral concentrations in the body by excreting the excess amounts in urine. Toxicity symptoms from excess intakes are more likely to appear with acute or **chronic kidney failure**.

Trace minerals can be toxic at higher intakes, especially for those minerals whose absorption is not regulated in the body (e.g., selenium and iodine). Thus, it is important not to habitually exceed the recommended intake levels. Although toxicity from dietary sources is unlikely, certain genetic disorders can make people vulnerable to overloads from food or supplements. One such disorder, hereditary **hemochromatosis**, is characterized by iron deposition in the liver and other tissues due to increased intestinal iron absorption over many years.

Chronic exposure to trace minerals through cooking or storage containers can result in overloads of iron, zinc, and copper. Fluorosis, a discoloration of the teeth, has been reported in regions where the natural content of fluoride in drinking water is high. Inhalation of manganese dust over long periods of time has been found to cause brain damage among miners and steelworkers in many parts of the world.

Disease prevention and treatment

In addition to clinical deficiency diseases such as anemia and goiter, research indicates that trace minerals play a role in the development, prevention, and treatment of chronic diseases. A marginal status of several trace minerals has been found to be associated with infectious diseases, disorders of the stomach, intestine, bone, heart, and liver, and cancer, although further research is necessary in many cases to understand the effect of supplementation. Iron, zinc, copper, and selenium have been associated with immune response conditions. Copper, chromium and selenium have been linked to the prevention of cardiovascular disease. Excess iron in the body, on the other hand, can increase the risk of cardiovascular disease, liver and colorectal cancer, and neurodegenerative diseases such as Alzheimer's disease. Chromium supplementation has been found to be beneficial in many studies of impaired glucose tolerance, a metabolic state between normal glucose regulation and diabetes. Fluoride has been known to prevent dental caries and **osteoporosis**, while potassium iodide supplements taken immediately before or after exposure to radiation can decrease the risk of radiation-induced **thyroid cancer**.

Sodium, chloride, and potassium are linked to high blood pressure (**hypertension**) due to their role in the body's fluid balance. High salt or sodium chloride intake has been linked to cardiovascular disease as well. High potassium intakes, on the other hand, have been associated with a lower risk of stroke, particularly

in people with hypertension. Research also suggests a preventive role for magnesium in hypertension and cardiovascular disease, as well as a beneficial effect in the treatment of diabetes, osteoporosis, and migraine headaches.

Sodium and chloride toxicity can develop due to low intake or excess loss of water. Accumulation of excess potassium in plasma may result from the use of potassium-sparing diuretics (medications used to treat high blood pressure, which increase urine production, excreting sodium but not potassium), insufficient aldosterone secretion (a hormone that acts on the kidney to decrease sodium secretion and increase potassium secretion), or tissue damage (e.g., from severe **burns**). Magnesium intake from foods has no adverse effects, but a high intake from supplements when kidney function is limited increases the risk of toxicity. The most serious complication of potassium or magnesium toxicity is cardiac arrest. Adverse effects from excess calcium have been reported only with consumption of large quantities of supplements. Phosphate toxicity can occur due to absorption from phosphate salts taken by mouth or in **enemas**.

Osteoporosis is a bone disorder in which bone strength is compromised, leading to an increased risk of fracture. Along with other lifestyle factors, intake of calcium and vitamin D plays an important role in the maintenance of bone health and the prevention and treatment of osteoporosis. Good calcium nutrition, along with low salt and high potassium intake, has been linked to prevention of hypertension and **kidney stones**.

Interactions

Some body processes require several minerals to work together. For example, calcium, magnesium, and phosphorus are all important for the formation and maintenance of healthy bones. Some minerals compete with each other for absorption, and they interact with other nutrients as well, which can affect their bioavailability.

With the exception of iron, dietary deficiencies are rare in the United States and other developed nations. However, **malnutrition** in developing countries increases the risk for trace-mineral deficiencies among children and other vulnerable groups. In overzealous supplement users, interactions among nutrients can inhibit absorption of some minerals leading to deficiencies. Patients on intravenous feedings without mineral supplements are at risk of developing deficiencies as well.

KEY TERMS

Absorption—Uptake by the digestive tract.

Bioavailability—Availability to living organisms, based on chemical form.

Caries—Cavities in the teeth.

Cretinism—Arrested mental and physical development.

Fortified—Altered by addition of vitamins or minerals.

Myoglobin—Oxygen storage protein in muscle.

Neurotransmitter—Molecule released by one nerve cell to stimulate or inhibit another.

Phytate—Plant compound that binds minerals, reducing their ability to be absorbed.

Complications

Mineral supplementation may be appropriate for people with prolonged illnesses or extensive injuries, for those undergoing surgery, or for those being treated for alcoholism. However, extra caution must be taken to avoid intakes greater than the RDA or AI for specific nutrients because of problems related to nutrient excesses, imbalances, or adverse interactions with medical treatments. Although toxic symptoms or adverse effects from excess supplementation have been reported for various minerals (e.g., calcium, magnesium, iron, zinc, copper, and selenium) and tolerable upper limits set, the amounts of nutrients in supplements are not regulated by the Food and Drug Administration (FDA). Therefore, supplement users must be aware of the potential adverse effects and choose supplements with moderate amounts of nutrients.

REVISED BY LAURA JEAN CATALDO, RN, EdD

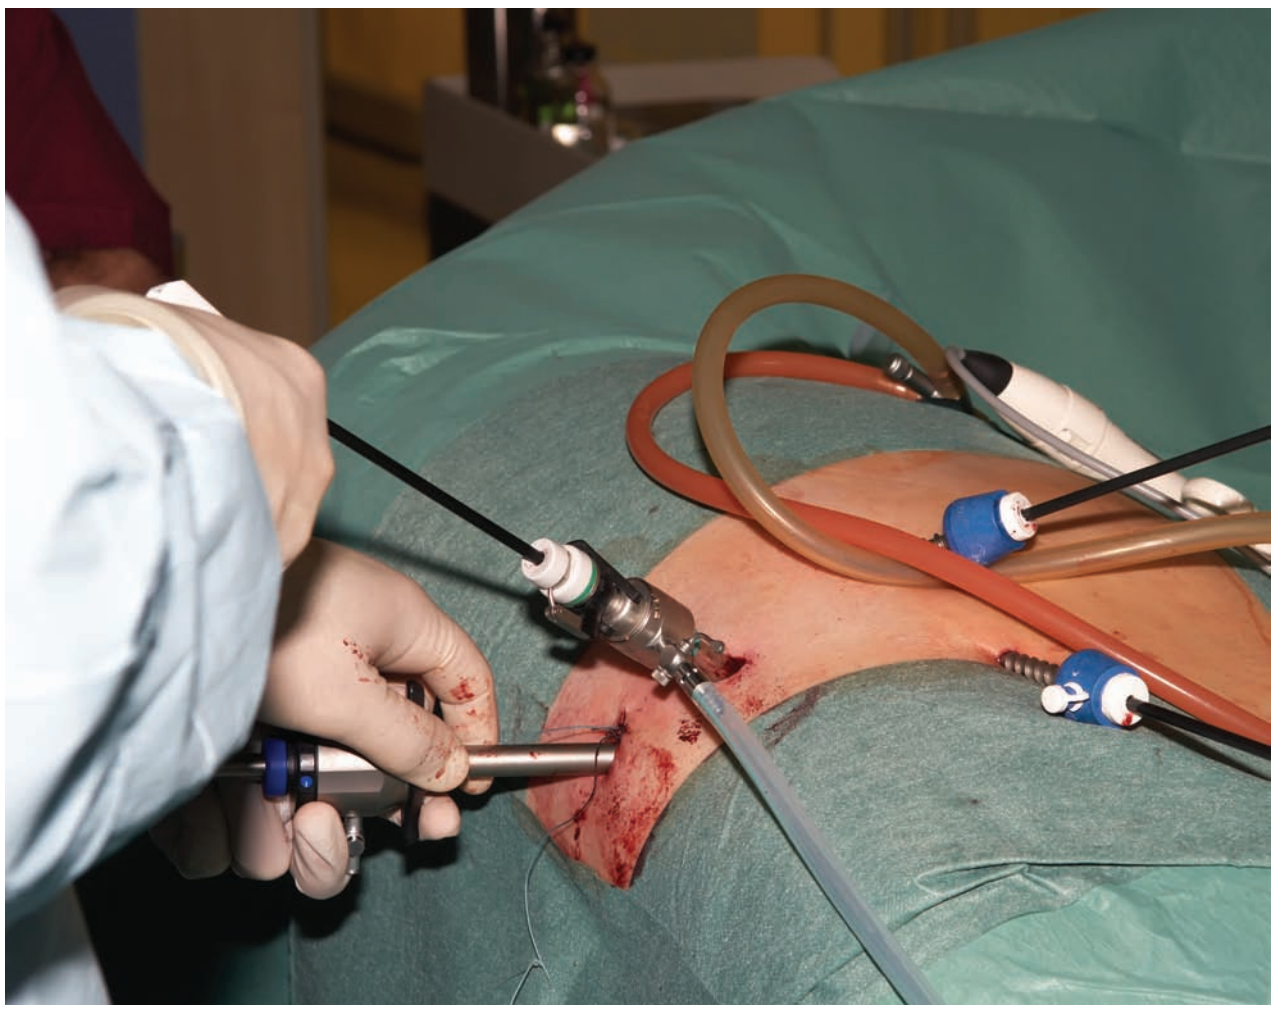
Minimally invasive surgery

Definition

Minimally invasive surgery is an alternative to open surgery. The technique uses no cuts or small cuts (incisions). The surgeon uses a small scope and tiny instruments to perform the same types of operations as with traditional open surgery, but without the long incision.

Purpose

Use of small incisions instead of a long one that opens up a patient's body makes recovery from surgery much less painful and much faster than with traditional open surgery. When a patient has open surgery to reach a structure deep within the abdomen or another part of the body, the surgeon must cut



Laparoscopic surgical operation. *(© Limpopo/Shutterstock.com)*

through several layers of muscle and soft tissue and make an incision large enough to see inside the area, insert instruments, and often to remove an organ, such as an infected appendix. In minimally invasive procedures, the surgeon makes a few tiny incisions, often making one near the navel to minimize scarring. The technique leads to shorter hospital stays and return to normal activity in less time than with open surgery. Because the technique is less invasive and in many instances safer, it has replaced open surgery for most patients receiving many operations today, such as appendectomies, or removal of the appendix, colectomy, which is surgery to remove portions of the colon, and **hysterectomy**, or removal of the uterus and sometimes other reproductive organs.

Description

Sometimes called laparoscopic surgery, minimally invasive surgery often involves use of a laparoscope. A laparoscope is one of several small "telescopes" that can be inserted into a tiny incision in the patient's body to assist in surgery. The laparoscope has a small camera mounted at the end that sends images to a monitor mounted in the operating room. The doctor inserts a port, or nozzle, into one of the cuts that sends a small amount of carbon dioxide gas into the area being treated to inflate it like a small balloon. This helps the surgeon more easily see the organs under the skin. The surgeon uses the scope and monitor to explore inside an opening, or cavity, in the patient's body and to guide the small instruments, called trochars, inserted through other tiny incisions.

Laparoscopic surgery

Laparoscopic surgery was the first popular form of minimally invasive surgery and most often was used for **gynecologic surgery**, or surgery involving the female reproductive organs. Originally, doctors used the scopes to perform procedures such as **tubal ligation**, or closing of the Fallopian tubes to prevent **pregnancy**, and for exploring a woman's reproductive organs to diagnose diseases and conditions. Today, the procedure is commonly used in gynecology to treat conditions such as **endometriosis**, and to perform hysterectomies. In a laparoscopically assisted vaginal hysterectomy, the doctor can evaluate and cut away a woman's uterus, along with the ovaries and Fallopian tubes if necessary, by using a laparoscope and other instruments inserted through tiny incisions in the woman's abdomen. The doctor removes the cut-away uterus and other organs through the woman's vagina.

Endoscopy

Minimally invasive procedures may be used to see inside a patient's body with no cuts or incisions necessary. Usually, this type of procedure is used to help diagnose disease by inserting the scope, which has a small video camera, into an existing cavity in a patient's body. As with other minimally invasive surgery, the procedures often have come to replace traditional open surgery, in which a surgeon would open a patient with a large incision to examine areas inside the patient's body. Examples include:

- Bronchoscopy, use of a tube called a bronchoscope that is passed through the mouth or nose to look at a patient's upper airways. It is usually used to diagnose lung disease.
- Colonoscopy, insertion of the scope into a patient's anus to view the colon and large intestine to diagnose polyps or colon and rectal cancer.
- Hysteroscopy, insertion of a scope into a woman's vagina and cervix to see inside the uterus.
- Sigmoidoscopy, insertion of a flexible scope into the anus to check the lower portion of the large intestine for polyps, cancer, or other signs of disease.

A laparoscope also is a type of endoscope, but it usually is inserted through cuts in the body. A mediastinoscope also is inserted into incisions in the chest area between the lungs.

Laparoscopic surgery for digestive diseases

In addition to an **appendectomy**, doctors who specialize in treating digestive diseases often use a laparoscopic approach for several procedures such as:

- Severe gastroesophageal reflux disease to correct the flow of acid back to the stomach
- Gallbladder stone removal, or laparoscopic cholecystectomy
- Hernia repair. A hernia occurs when the inner layers of the abdomen wall weaken or rip.

Interventional radiology and cardiac catheterization

Some of the most invasive and complex surgeries can involve the body's heart, lungs, and circulatory system. Minimally invasive procedures conducted by cardiovascular surgeons or interventional radiologists can evaluate and repair veins and blood vessels. Doctors use imaging, usually fluoroscopy, to guide their activity, and insert long, thin, flexible tubes called catheters just under a patient's skin and into a the

WWW.BOOKBAZ.IR

blood vessels. Examples of procedures performed on blood vessels include:

- Angiography, use of special dye and x rays to examine blood vessels for problems.
- Arteriovenous malformation correction. The radiologist guides a catheter to the AVM, an area of tangled blood vessels that can rupture without warning. Injecting a substance blocks blood supply to the tangled vessels to prevent rupture.
- Balloon angioplasty, insertion of a tiny balloon into narrowed or blocked blood vessels and inflating the balloon to open the vessels.
- Thrombolysis, dissolving of blood clots by injecting drugs at the site of the clot to break it up and help prevent stroke or to treat clots in the brain to reverse effects of a stroke.
- Varicose vein treatment. The doctor uses a laser or special radiofrequency waves to seal veins without surgery.

Minimally invasive heart surgery

Cardiovascular surgeons use similar methods to treat problems with the blood vessels and the heart. The surgeon can thread the thin catheter to a blocked artery in a patient's heart and use a balloon to open the blocked or narrow artery. The procedure is called **angioplasty** and is an alternative to coronary artery bypass grafting for some patients.

For minimally invasive surgery on the heart, the surgeon makes small incisions in the side of the chest between the patient's ribs to pass instruments through, and sometimes makes an incision near a patient's nipple. These methods can avoid the standard open heart procedure that typically requires a long incision in the chest and dividing the sternum, or breastbone, to reach the heart. Examples of minimally invasive heart surgery include:

- Maze procedure to treat atrial fibrillation. The surgeon makes several small incisions in the left and right atrium that will form scar tissue to stop the electrical signals that cause atrial fibrillation, or irregular heartbeat.
- Arteriovenous malformation correction. The radiologist guides a catheter to the AVM, an area of tangled blood vessels that can rupture without warning. Injecting a substance blocks blood supply to the tangled vessels to prevent rupture.
- Minimally invasive heart valve surgery, to repair a valve so that it works better or replace a diseased valve with a new one.
- Minimally invasive heart bypass surgery. Using several small incisions or one incision a few inches long, the surgeon can operate on the heart's arteries while the heart is still beating. Patients need no heart-lung machine or long incision.

Minimally invasive spine surgery

The spinal cord is an important and delicate nerve, responsible for sending signals to and from the brain. Any damage to the spinal cord could result in loss of movement or sensation below the damage, including **paralysis**. With minimally invasive spine surgery, neuroosurgeons and orthopedic surgeons can reduce **trauma** to the muscles and tissues around the spine and vertebra and reduce risk of damage to the spinal cord area. Some of the more common minimally invasive procedures surgeons perform on the spine are to correct degenerative disc disease, or damage to the soft discs that separate the bones of the vertebrae. Doctors also can treat herniated discs, deformities such as **scoliosis**, compression **fractures**, tumors, and infections.

Robotic surgery

The performance of minimally invasive surgery has advanced further in recent years with the addition of robotics. Tiny tools are attached to a robotic arm that the physician can control using specially designed software and three-dimensional images on a monitor. Using the same small incisions as scopes, the small robotic instruments can twist and bend further than possible for a human wrist, so that the surgeon can perform more detailed surgery within the patient's body. Robotics assist surgeries in nearly every medical specialty.

Teresa G. Odle, ELS

KEY TERMS

Neuropsychological testing—Tests used to evaluate patients who have experienced a traumatic brain injury, brain damage, or organic neurological problems (e.g., dementia). It may also be used to evaluate the progress of a patient who has undergone treatment or rehabilitation for a neurological injury or illness.

Norms—Normative or mean score for a particular age group.

Psychopathology—A mental disorder or illness, such as schizophrenia, personality disorder, or major depressive disorder.

Standardization—The process of determining established norms and procedures for a test to act as a standard reference point for future test results.

Minnesota multiphasic personality inventory (MMPI-2)

Definition

The Minnesota Multiphasic Personality Inventory (MMPI-2; MMPI-A) is a written psychological assessment, or test, used to diagnose mental disorders.

Purpose

The MMPI is used to screen for personality and **psychosocial disorders** in adults and adolescents. It is also frequently administered as part of a neuropsychological test battery to evaluate cognitive functioning.

Precautions

The MMPI should be administered, scored, and interpreted by a clinical professional trained in its use, preferably a psychologist or psychiatrist. The MMPI is only one element of psychological assessment, and should never be used alone as the sole basis for a diagnosis. A detailed history of the test subject and a review of psychological, medical, educational, or other relevant records are required to lay the groundwork for interpreting the results of any psychological measurement.

Cultural and language differences in the test subject may affect test performance and may result in inaccurate MMPI results. The test administrator should be informed before psychological testing begins if the test taker is not fluent in English and/or has a unique cultural background.

Description

The original MMPI was developed at the University of Minnesota and introduced in 1942. The current standardized version for adults 18 and over, the MMPI-2, was released in 1989, with a subsequent revision of certain test elements in early 2001. The MMPI-2 has 567 items, or questions, and takes approximately 60 to 90 minutes to complete. There is a short form of the test that is comprised of the first 370 items on the long-form MMPI-2. There is also a version of the inventory for adolescents age 14 to 18, the MMPI-A.

The questions asked on the MMPI are designed to evaluate the thoughts, emotions, attitudes, and behavioral traits that comprise personality. The results of the test reflect an individual's personality strengths and weaknesses, and may identify certain disturbances of personality (psychopathologies) or mental deficits caused by neurological problems.

There are six validity scales and ten basic clinical or personality scales scored in the MMPI-2, and a number of supplementary scales and subscales that may be used with the test. The validity scales are used to determine whether the test results are actually valid (i.e., if the test-taker was truthful, answered cooperatively and not randomly) and to assess the test-taker's response style (i.e., cooperative, defensive). Each clinical scale uses a set or subset of MMPI-2 questions to evaluate a specific personality trait. The MMPI should always be administered in a controlled environment by a psychologist or other qualified mental health professional trained in its use.

WWW.BOOKBAZ.IR

Preparation

The administrator should provide the test subject with information on the nature of the test and its intended use, complete standardized instructions to taking the MMPI (including any time limits, and information on the confidentiality of the results).

Normal results

The MMPI should be scored and interpreted by a trained professional. When interpreting test results for test subjects, the test administrator will review what the test evaluates, its precision in evaluation and any margins of error involved in scoring, and what the individual scores mean in the context of overall norms for the test and the background of the test subject.

Minor tranquilizers *see* **Antianxiety drugs**

Minority health

Definition

Minority health covers the special medical and/or health needs associated with specific ethnic and racial groups—those that are among the minority populations within the United States.

Demographics

As stated by the Office of Minority Health (part of the U.S. Department of Health and Human Services), some minority groups include Native Americans and Alaska Natives, Asian Americans, Blacks/African Americans, Hispanics/Latinos, Native Hawaiians, and other Pacific Islanders. The Office of Minority Health is a leader in the U.S. government's Health and Human Services (HHS) Action Plan to Reduce Racial and Ethnic Health Disparities. This initiative, built upon the fundamentals of the Affordable Care Act, promotes best practices for minority populations and is in sync with other initiatives, including Healthy People 2020, the First Lady's Let's Move, and the President's National HIV/AIDS Strategy.

During the twenty-first century, it is anticipated that minority groups will grow as a percentage of the population in the United States. The overall health statistics of the nation will parallel the health of these groups.

Description

The United States has considerable cultural and ethnic diversity. Specific health problems or patterns correlate to specific ethnic or racial groups and pose particular problems for service and medical agencies. These specific health issues include infant mortality rates, cancer, cardiovascular disease, diabetes, HIV (human **immunodeficiency** virus) infection, and immunizations.

Infant mortality rates

Infant mortality rates (IMRs) in the United States and in all countries worldwide are an accurate indicator of health status. They provide information concerning programs about **pregnancy** education and counseling, technological advances, and procedures and aftercare. IMRs vary among racial groups. The IMR in the United States, in 2014, was estimated to be 6.17 per 1,000 live births, according to the Central Intelligence Agency.

The Centers for Disease Control and Prevention indicate the non-Hispanic white IMR as 5.18 per 1,000 live births. African Americans had an IMR of 11.46 per 1,000 live births. The IMRs among American Native Indian groups varies greatly, with some communities possessing IMRs about two times greater than national rates. Overall Native Americans had an IMR of 8.1. Additionally, IMRs for Hispanic Americans vary a great deal between groups. However the overall IMR for Hispanic Americans is 5.25 per 1,000 live births. The IMRs for example among Puerto Rican Americans is higher (8.3 per 1,000 live births) while with Mexican Americans it is lower (5.5 per 1,000 live births). Asian- and Pacific Islander Americans IMR averages 4. Central Americans and South-Americans IMR is 4.7, and Cuban Americans IMR is 4.4 per 1,000 live births. (Statistics for the various minority groups were provided by the U.S. Centers for Disease Control and Prevention.)

Cancer

Cancer is a serious national, worldwide, and minority health concern. In 2014, the American Cancer Society estimated more than 1.6 million new cases of cancer would be diagnosed. It is the second cause of death in the United States, claiming over half a million lives each year (approximately 585,000 in 2014, according to the American Cancer Society). Approximately 50% of persons who develop cancer will die from it.

There is great disparity among the cancer rates in minority groups. Across genders, cancer death rates for African Americans are 20% higher than for Caucasian Americans. The death rates for **prostate cancer** (more than two times more) and other cancers are disproportionately higher when compared to Caucasians. In addition, Hispanic men and women have higher incidence and mortality rates for stomach and **liver cancer** than non-Hispanic whites.

Alaskan native men and women have a greater propensity for cancers in the rectum and colon than do Caucasians. American/Alaskan Native men are more at risk for liver and **stomach cancer**, when compared to non-Hispanic white men. Asian American men are more prone to stomach cancer than are non-Hispanic white men. Asian and Pacific Islander Americans will develop stomach cancer more often than non-Hispanic American whites.

There are also gender differences among ethnic groups and specific cancers. Lung cancers in African American men are higher when compared with Caucasian males. Hispanic and African American females have a greater incidence of **cervical cancer** than Caucasian females.

Cardiovascular disease

Cardiovascular disease is the leading cause of disability, and death rates are about equal to deaths from all other diseases combined. Cardiovascular disease can affect the patient's lifestyle and function in addition to having an impact on family members. The financial costs are very high. Among ethnic and racial groups, cardiovascular disease is the leading cause of death. Forty-one percent of African Americans have high blood pressure, more than other ethnic group in the world. However, African Americans and non-Hispanic white Americans have similar rates of **heart disease**. Despite the same rates of disease, African American males are three times more likely to die from heart disease than are white males.

Stroke is the leading cause of cardiovascular-related death, which occurs in higher numbers for Asian American males when compared to Caucasian men. Mexican American men and women and African-American males have a higher incidence of **hypertension**. African American women have higher incidence of overweight, which is a major risk factor of cardiovascular disease. Mexican Americans, African Americans, Native Hawaiian/Pacific Islanders, and Native Americans/Alaskan Natives also have higher rates of **obesity** than do other groups.

Diabetes

Diabetes—a serious health problem in Americans in general and ethnic groups in particular—is the seventh leading cause of death in the United States, and the disease affects more than 25 million American adults. About 40% of all American adults have prediabetes. Racial and ethnic minorities are especially at risk for diabetes. The prevalence of diabetes in African Americans is about twice that of Caucasians, according to the Office of Mental Health. The elderly within the African American population is especially at risk for diabetes, even more so for women over the age of 75 (diabetes is anticipated to increase by 606% in that group by 2050). Diabetes is also common in older Hispanics. Native Americans and Alaska Natives have approximately double the risk for diabetes than do non-Hispanic whites.

Family planning

In the United States, socioeconomic and ethnic/racial disparities are found regarding family planning issues such as unplanned pregnancy and births, as well as abortion. Women in ethnic and racial minorities, as well as those in poorer socioeconomic groups, have higher rates of adolescent pregnancy and **childbirth**. The Hispanic population has experienced the highest rate of adolescent childbirth.

A study released in 2010 identified three factors contribute to this problem:

- preferences and behaviors of the women concerning contraception and pregnancy
- lack of access to health care
- inequitable treatment by healthcare providers

HIV

HIV infection/AIDS (acquired immune deficiency syndrome) is the most common cause of death for all persons age 25 to 44 years old. Ethnic groups account for about 25% of the U.S. population and more than

WWW.BOOKBAZ.IR

two-thirds of all recently diagnosed **AIDS** cases, according to the Centers for Disease Control and Prevention (CDC). In addition, about 75% of all babies born with HIV/AIDS are from minority groups in the United States. Besides an increase of sexual transmission of HIV/AIDS within the minority communities, there is also an increase in HIV among ethnic groups related to intravenous drug usage. Specifically, African Americans, both men and women, are more likely to die from AIDS than are non-Hispanic white men.

Immunizations

Between 1989 and 1991, there was a spike in the number of **measles** cases in the United States with more than 55,000 cases reported and more than 100 deaths. Children of American Indian, Hispanic, non-Hispanic African American, and low-income levels were disproportionately the victims of this measles outbreak. In response to this, in 1993, the Childhood Immunization Initiative was developed to eliminate the disparity in **vaccination** rates. In 1994, the Vaccines for Children (VFC) program was launched, administering no-cost vaccines to children whose families cannot afford to pay for them. As a result, the disparity between minority groups and whites receiving immunizations and the reduction of preventable disease has narrowed over the past years. However, there are still smaller percentages of minority adults being immunized when compared to white adults. Overall, immunization rates among all groups are much higher than compared to adults. In the 2012–2013 flu season, non-Hispanic, African Americans were less represented in receiving the vaccine than people of other races. The American Asian population had a higher proportion of vaccine than other races. Non-Hispanic whites had more vaccine coverage than non-Hispanic African Americans and Hispanics.

Tuberculosis is a disease that is controlled by immunizations. However, Asian and Pacific Islander Americans were 23 times more at risk for contracting tuberculosis (TB) than were non-Hispanic whites. **Hepatitis B** is another disease controlled with vaccines. Even though rates of hepatitis B continue to decline in the United States in the twenty-first century, its rate is twice as high for non-Hispanic blacks when compared to non-Hispanic whites. A study released in 2014 revealed that tuberculosis affects a disproportionate number of U.S. residents who were born in Mexico, China, the Philippines, India, and Vietnam. The study examined 9,588 new cases of tuberculosis in the United States, and found that more than 64% of these cases involved persons born outside the United States.

Causes and symptoms

IMRs are correlated with prenatal care. Women who receive adequate prenatal care tend to have better pregnancy outcomes when compared to little or no care. Women who receive inadequate prenatal care also have increased chances of delivering a very low birth weight (VLBW) infant, which is linked to risk of early death.

Cancer is related to several preventable lifestyle choices. Tobacco use, diet, and exposure to the sun (**skin cancer**) can be prevented by lifestyle modifications. Additionally many cancers can occur due to lack of interest in and/or lack of availability for screening and educational programs.

Cardiovascular diseases are higher among persons with high blood **cholesterol** and high blood pressure. Certain lifestyle choices may increase the chance for heart disease includes lack of **exercise**, overweight, and cigarette **smoking**. Cardiovascular disease is responsible for over 50% of the deaths in persons with diabetes.

HIV occurs at a higher frequency among homosexuals (the number of African American males who have AIDS through sex with men has increased). Additionally unprotected sexual intercourse and sharing used needles for IV drug injection are strongly correlated with infection.

Vaccinations are an effective method of preventing certain disease such as **polio**, **tetanus**, pertussis, **diphtheria**, **influenza**, hepatitis b, and pneumococcal infections. Approximately 90% of influenza related mortality is associated with persons aged 65 and older. This is mostly due to neglect of vaccinations. About 45,000 adults each year die of diseases related to hepatitis B, pneumococcal, and influenza infections.

Diagnosis

The diagnosis of VLBW is by weight. Infants who weigh 1,500 grams (1.5 kilograms, or 3.3 pounds) at birth are at high risk for death. For cancer, the diagnosis can be made through screening procedures such as **mammography** (for **breast cancer**), PAP smear (PAP is short for papanicolau, which is used to identify cervical cancer), and lifestyle modifications such as avoidance of ultraviolet rays from the Sun (and artificially produced radiation, such as from **tanning** beds), cigarette smoking, balanced **diets**, and adequate

KEY TERMS

Prevalence—Number of existing cases relative to time.

Propensity—A greater risk for developing a disease.

nutrition. Other specific screening tests (PSA, prostate surface antigen) are helpful for diagnosing prostate cancer.

Cardiovascular diseases can be detected by medical check-ups. Blood pressure and cholesterol levels can be measured. Obesity can be diagnosed by assessing a person's weight relative to the person's height (what is called BMI, or **body mass index**). Diabetes and its complications can be detected by blood tests, in-depth eye examinations, and studies that assess the flow of blood through blood vessels in legs. HIV can be detected through a careful history/physical examination and analysis of blood using a special test called a western blot. Infections caused by lack of immunizations can either be detected by careful **physical examination** and culturing the specific microorganism in the laboratory.

Treatment

Cancer may require treatment utilizing surgery, radiotherapy, or **chemotherapy**. Cardiovascular diseases may require surgical procedures for establishing a diagnosis and initiating treatment. Depending on the extent of disease, cardiovascular management can become complicated requiring medications and daily lifestyle modifications. Treatment usually includes medications, dietary modifications, and—if complications arise—specific interventions tailored to alleviating the problem. HIV can be treated with specific medications and more often than not with symptomatic treatment as reported complications arise. Diseases caused by lack of immunizations are treated based on the primary disease. The best method of treatment is through prevention and generating public awareness through education.

Alternatives

Alternative therapies do exist, but more research is needed to substantiate present data. The diseases that relate to minority health are best treated with nationally accepted standards of care.

Prognosis

Generally the prognosis is related to the diagnosis, patients' state of health, age, and if there is another disease or complication in addition to the presenting problem. The course for IMRs is related to educational programs and prenatal care, which includes medical and psychological treatments. The prognosis for chronic diseases such as cardiovascular problems, high blood pressure, cancer, and diabetes is variable. These diseases are not cured, and control is achieved by standardized treatment options. Complications, even with treatment, can occur. For HIV the clinical course at present is death even though this process may take years. Educational programs with an emphasis on disease prevention can potentially improve outcomes concerning pediatric and geriatric diseases.

Prevention

Prevention is accomplished best through educational programs specific to target populations. IMRs can be prevented by increasing awareness, interest, and accessibility for prenatal care. Regular physicals and special screening tests can potentially prevent certain cancers in high-risk groups. Educational programs concerning lifestyle modifications, diet, exercise, and testing may prevent the development of cardiovascular disease and diabetes. Educational programs may also be beneficial to illicit IV drug abusers and persons who engage in unprotected sexual intercourse.

All adults in the United States should be proactive, making sure to get information on those preventable diseases they are at most risk for acquiring and for which vaccines are available. Parents should make sure that their children have been fully vaccinated by the age of two years. Caregivers of vulnerable and/or aging individuals should confirm that appropriate vaccines are given to their charges.

The importance of diagnosing, treating, and preventing minority health problems over the next decade will become increasingly important. The U.S. Census Bureau estimates that by 2100, only about 40% of the U.S. population will consist of non-Hispanic whites. As minority groups become larger, their health has greater effect on the whole society. In order to improve the overall health of the society, disparities among ethnic groups regarding health and medical services need to be eliminated, and all individuals regardless of ethnic or racial identity need to be similarly served.

Minoxidil

Definition

Minoxidil is a drug that is available in two forms: as a solution or foam, Rogaine, applied topically to the scalp to promote hair growth, and as tablets, Loniten, to treat high blood pressure.

Purpose

Hair growth and the reversal of male pattern baldness was a side effect noted when Loniten was used to treat high blood pressure. How it stimulates hair growth is not known.

Rogaine solution and foam, in 2% and 5% concentrations, are available in the United States without a prescription.

Rogaine is more likely to be effective in men and women under age 40. It must be used daily for up to three months before hair growth become noticeable. Once daily use is stopped, hair loss begins again.

Minoxidil does not work for everyone. Forty-eight percent of men who use it for one year can expect to see moderate to dense regrowth of hair; 36% minimal regrowth, and 16% no regrowth.

Women and men respond similarly to topical minoxidil.

Minoxidil tablets, orally, is only used for treating severe high blood pressure and has serious has side effects that generally require using additional medications.

Precautions

It is important to carefully follow the package directions for the amount to use (dose) and proper application and handling of minoxidil solution or foam.

Minoxidil should not be used 24 hours before or after applying hair treatments such as coloring, permanent or relaxer. Before applying these treatments, the hair should be thoroughly washed and dried.

After applying minoxidil, hands should be thoroughly washed.

To reduce the risk of absorption through the skin, Minoxidil should be used only on small areas of the scalp.

People with sunburns and/or chronic skin or scalp **rashes** or conditions may absorb minoxidil into their bodies and run a greater risk of side effects.

People who have had unusual or allergic skin reactions to dyes and preservatives may be at greater risk for allergic reactions to minoxidil foam or solution.

People who use cortisone creams or ointments, petroleum jelly (Vaseline), or tretinoin (Retin-A) on their scalps risk absorbing more minoxidil into their bodies and experiencing side effects.

Minoxidil enters breast milk and is not recommended for use in nursing mothers.

Preparation

Before applying topical minoxidil, the hair and scalp should be clean and dry.

Aftercare

Immediately after applying minoxidil, hands and other areas of the body that may have come into contact with the drug, where hair growth is not desired, should be washed.

Do not wash hair for four hours after applying minoxidil.

Topical minoxidil should be allowed to air-dry for two to four hours before clothing is pulled on or off over the head, a hat is worn, or the person using it goes to bed. Minoxidil may stain clothing, hats, or bed linens.

Risks

More common side effects from using topical minoxidil include **itching**, burning, redness, and tenderness over hair roots in treated areas. These usually go away within a couple weeks.

Unwanted hair growth may occur adjacent to treated areas or in areas where the medicine has been inadvertently transferred.

Side effects that may occur if topically minoxidil is absorbed into the body include:

- changes in vision, most commonly blurred vision
- chest pain
- dizziness
- rapid or irregular pulse
- very low blood pressure
- fast or irregular heartbeat
- flushing of the skin
- headache
- lightheadedness
- numbness or tingling in the hands, feet, or face
- rapid weight gain
- swelling of the hands, feet, lower legs, or face

Normal results

When new growth begins, the first hairs may be soft and barely visible. For some, this is the extent of the effectiveness of this medication. For others, the down-like hair develops into hair of the same color and thickness as the other hairs on their head.

Minoxidil is a treatment, not a cure, for hair loss. Once a person stops using it, the re-grown hair will be lost within 90 days.

Miscarriage

Definition

Miscarriage means loss of an embryo or fetus before the 20th week of **pregnancy**. Most miscarriages occur during the first 14 weeks of pregnancy. The medical term for miscarriage is spontaneous abortion.

Description

Miscarriages are very common. Approximately 20% of pregnancies (one in five) end in miscarriage. The most common cause is a genetic abnormality of the fetus. Not all women realize that they are miscarrying and others may not seek medical care when it occurs.

A miscarriage is often a traumatic event for both partners, and can cause feelings similar to the loss of a child or other member of the family. Fortunately, 90% of women who have had one miscarriage subsequently have a normal pregnancy and healthy baby; 60% are able to have a healthy baby after two miscarriages. Even a woman who has had three miscarriages in a row still has more than a 50% chance of having a successful pregnancy the fourth time.

Causes and symptoms

There are many reasons why a woman's pregnancy ends in miscarriage. Often the cause is not clear. However, more than half the miscarriages that occur in the first eight weeks of pregnancy involve serious chromosomal abnormalities or **birth defects** that would make it impossible for the baby to survive. These are different from inherited genetic diseases. They probably occur during development of the specific egg or sperm, and therefore are not likely to occur again.

In about 17% of cases, miscarriage is caused by an abnormal hormonal imbalance that interferes with the ability of the uterus to support the growing embryo. This is known as luteal phase defect. In another 10% of cases, there is a problem with the structure of the uterus or cervix. This can occur in women whose mothers used diethylstilbestrol (DES) when pregnant with them.

The risk of miscarriage is increased by:

- Smoking (up to a 50% increased risk)
- Infection
- Exposure to toxins (such as arsenic, lead, formaldehyde, benzene, and ethylene oxide)
- Multiple pregnancy
- Poorly controlled diabetes

The most common symptom of miscarriage is bleeding from the vagina, which may be light or heavy. However, bleeding during early pregnancy is common and is not always serious. Many women have slight vaginal bleeding after the egg implants in the uterus (about 7-10 days after conception), which can be mistaken for a threatened miscarriage. A few women bleed at the time of their monthly periods through the pregnancy. However, any bleeding in the first three months of pregnancy (first trimester) is considered a threat of miscarriage.

Women should not ignore vaginal bleeding during early pregnancy. In addition to signaling a threatened miscarriage, it could also indicate a potentially life-threatening condition known as **ectopic pregnancy**. In an ectopic pregnancy, the fetus implants at a site other than the inside of the uterus. Most often this occurs in the fallopian tube.

Cramping is another common sign of a possible miscarriage. The cramping occurs because the uterus attempts to push out the pregnancy tissue. If a pregnant woman experiences both bleeding and cramping the possibility of miscarriage is more likely than if only one of these symptoms is present.

If a woman experiences any sign of impending miscarriage, she should be examined by a practitioner. The doctor or nurse will perform a **pelvic exam** to check if the cervix is closed as it should be. If the cervix is open, miscarriage is inevitable and nothing can preserve the pregnancy. Symptoms of an inevitable miscarriage may include dull relentless or sharp intermittent **pain** in the lower abdomen or back. Bleeding may be heavy. Clotted material and tissue (the placenta and embryo) may pass from the vagina.

A situation in which only some of the products in the uterus have been expelled is called an incomplete miscarriage. Pain and bleeding may continue and become severe. An incomplete miscarriage requires medical attention.

A "missed abortion" occurs when the fetus has died but neither the fetus nor placenta is expelled. There may not be any bleeding or pain, but the symptoms of pregnancy will disappear. The physician may suspect a missed abortion if the uterus does not continue to grow. The physician will diagnose a missed abortion with an **ultrasound** examination.

A woman should contact her doctor if she experiences any of the following:

- Any bleeding during pregnancy
- Pain or cramps during pregnancy
- Passing of tissue
- Fever and chills during or after miscarriage

Diagnosis

If a woman experiences any sign of impending miscarriage she should see a doctor or nurse for a pelvic examination to check if the cervix is closed, as it should be. If the cervix is open, miscarriage is inevitable.

An ultrasound examination can confirm a missed abortion if the uterus has shrunk and the patient has had continual spotting with no other symptoms.

Treatment

Threatened miscarriage

For women who experience bleeding and cramping, bed rest is often ordered until symptoms disappear. Women should not have sex until the outcome of the threatened miscarriage is determined. If bleeding and cramping are severe, women should drink fluids only.

Miscarriage

Although it may be psychologically difficult, if a woman has a miscarriage at home she should try to collect any material she passes in a clean container for analysis in a laboratory. This may help determine why the miscarriage occurred.

An incomplete miscarriage or missed abortion may require the removal of the fetus and placenta by a D&C (**dilatation and curettage**). In this procedure the contents of the uterus are scraped out. It is performed in the doctor's office or hospital.

After miscarriage, a doctor may prescribe rest or **antibiotics** for infection. There will be some bleeding from the vagina for several days to two weeks after miscarriage. To give the cervix time to close and avoid possible infection, women should not use tampons or have sex for at least two weeks. Couples should wait for one to three normal menstrual cycles before trying to get pregnant again.

Prognosis

A miscarriage that is properly treated is not life-threatening, and usually does not affect a woman's ability to deliver a healthy baby in the future.

Feelings of grief and loss after a miscarriage are common. In fact, some women who experience a miscarriage suffer from major depression during the six months after the loss. This is especially true for women who don't have any children or who have had depression in the past. The emotional crisis can be similar to that of a woman whose baby has died after birth.

KEY TERMS

Diethylstilbestrol (DES)—A synthetic estrogen that is used to treat a number of hormonal conditions. However, it causes problems in developing fetuses and should not be taken during pregnancy. From about 1938 to 1971, DES was given to pregnant women because it was thought to prevent miscarriage. Children of women who took the drug during pregnancy are at risk for certain health problems.

Dilatation and curettage (D and C)—A procedure in which the neck of the womb (cervix) is expanded and the lining of the uterus is scraped to remove pregnancy tissue or abnormal tissue.

Embryo—An unborn child in the first eight weeks after conception. After the eighth week until birth, the baby is called a fetus.

Prevention

The majority of miscarriages cannot be prevented because they are caused by severe genetic problems determined at conception. Some doctors advise women who have a threatened miscarriage to rest in bed for a day and avoid sex for a few weeks after the bleeding stops. Other experts believe that a healthy woman (especially early in the pregnancy) should continue normal activities instead of protecting a pregnancy that may end in miscarriage later on, causing even more profound distress.

If miscarriage was caused by a hormonal imbalance (luteal phase defect), this can be treated with a hormone called progesterone to help prevent subsequent miscarriages. If structural problems have led to repeated miscarriage, there are some possible procedures to treat these problems. Other possible ways to prevent miscarriage are to treat genital infections, eat a well-balanced diet, and refrain from **smoking** and using recreational drugs.

Mitral incompetence *see* **Mitral valve insufficiency**

Mitral regurgitation *see* **Mitral valve insufficiency**

Mitral stenosis *see* **Mitral valve stenosis**

KEY TERMS

Aorta—A large artery beginning at the base of the left ventricle.

Atrium—One of the two upper chambers of the heart.

Rheumatic fever—An illness that sometimes follows a streptococcal infection of the throat.

Ventricle—One of the two lower chambers of the heart.

Mitral valve insufficiency

Definition

Mitral valve insufficiency is a term used when the valve between the upper left chamber of the heart (atrium) and the lower left chamber (ventricle) does not close well enough to prevent back flow of blood when the ventricle contracts. Mitral valve insufficiency is also known as mitral valve regurgitation or mitral valve incompetence.

Description

Normally, blood enters the left atrium of the heart from the lungs and is pumped through the mitral valve into the left ventricle. The left ventricle contracts to pump the blood forward into the aorta. The aorta is a large artery that sends oxygenated blood through the circulatory system to all of the tissues in the body. If the mitral valve is leaky due to mitral valve insufficiency, it allows some blood to get pushed back into the atrium. This extra blood creates an increase in pressure in the atrium, which then increases blood pressure in the vessels that bring the blood from the lungs to the heart. Increased pressure in these vessels can result in increased fluid buildup in the lungs.

Causes and symptoms

In the past, **rheumatic fever** was the most common cause of mitral valve insufficiency. However, the increased use of **antibiotics** for **strep throat** has made rheumatic **fever** rare in developed countries. In these countries, mitral valve insufficiency caused by rheumatic fever is seen mostly in the elderly. In countries with less developed health care, rheumatic fever is still common and is often a cause of mitral valve insufficiency.

Heart attacks that damage the structures that support the mitral valve are a common cause of mitral valve insufficiency. Myxomatous degeneration can cause a "floppy" mitral valve that leaks. In other cases, the valve simply deteriorates with age and becomes less efficient.

People with mitral valve insufficiency may not have any symptoms at all. It is often discovered during a doctor's visit when the doctor listens to the heart sounds.

Both the left atrium and left ventricle tend to get a little bigger when the mitral valve does not work properly. The ventricle has to pump more blood so it gets bigger to increase the force of each beat. The atrium gets bigger to hold the extra blood. An enlarged ventricle can cause **palpitations**. An enlarged atrium can develop an erratic rhythm (**atrial fibrillation**), which reduces its efficiency and can lead to **blood clots** forming in the atrium.

Diagnosis

When the doctor listens to the heart sounds, mitral valve insufficiency is generally recognized by the sound the blood makes as it leaks backward. It sounds like a regurgitant murmur. The next step is generally a chest x ray and an electrocardiogram (ECG) to see if the heart is enlarged. The most definitive noninvasive test is **echocardiography**, a test that uses sound waves to make an image of the heart. This test gives a picture of the valve in action and shows the severity of the problem.

Treatment

A severely impaired valve needs to be repaired or replaced. Either option will require surgery. Repairing the valve can fix the problem completely or reduce it enough to make it bearable and prevent damage to the heart. Valves can be replaced with either a mechanical valve or one that is partly mechanical and partly from a pig's heart.

Mechanical valves are effective but can increase the incidence of blood clots. To prevent blood clots from forming, the patient will need to take drugs that prevent abnormal blood clotting (anticoagulants). The valves made partly from a pigs heart do not have as great a risk of blood clots but don't last as long as fully mechanical valves. If a valve wears out, it must be replaced again.

Damaged heart valves are easily infected. Anytime a procedure is contemplated that might allow infectious organisms to enter the blood, the person with mitral valve insufficiency should take antibiotics to prevent possible infection.

Prognosis

The diagnostic, medical and surgical procedures available to the person with mitral valve insufficiency are all likely to produce good results.

Prevention

The only possible way to prevent mitral valve insufficiency is to prevent rheumatic fever. This can be done by evaluating sore throats for the presence of the bacteria that causes strep throat. Strep throat is easily treated with antibiotics.

Dorothy Elinor Stonely

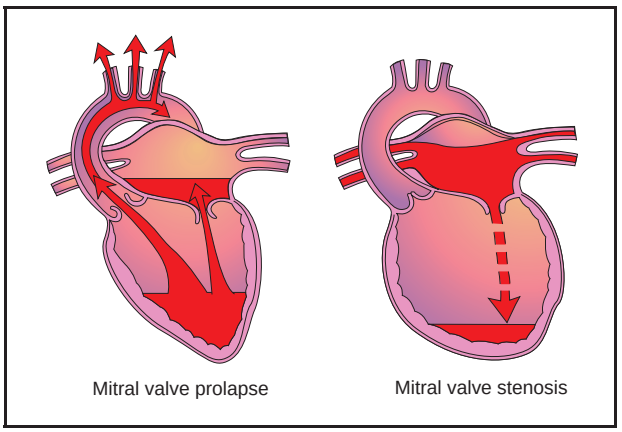
Mitral valve prolapse

Definition

Mitral valve prolapse (MVP) is a ballooning of the support structures of the mitral heart valve into the left upper collection chamber of the heart.

Description

Other names for MVP include floppy valve and Barlow's syndrome. The mitral valve is located on the left side of the heart between the top chamber (left atrium) and the bottom chamber (left ventricle). The valve opens and closes according to the heartbeat and the pressure that is exerted upon it from the blood in both chambers.



Mitral valve prolapse occurs when the mitral valve does not open and close properly. When this happens, the valve may balloon into the left atrium of the heart, causing the mitral valve to leak blood backward. Mitral valve stenosis refers to the narrowing of the mitral valve, in which the flow of blood from the atrium to the ventricle becomes restricted. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

The valve has supporting structures that attach to the heart muscle to help it open and close properly. When these structures weaken or lengthen abnormally, the valve may balloon into the left atrium. Sometimes this can cause the mitral valve to leak blood backward.

This condition may be inherited and occurs in approximately 10% of the population. It affects more women than men and often peaks after the age of 40.

Causes and symptoms

MVP may occur due to rheumatic **heart disease** but is usually found in healthy people. Changes that occur in the valve are caused by rapid multiplication of cells in the middle layer that presses on the outer layer. The outer layer weakens, causing a prolapse of the valve toward the left atrium.

Most persons do not have symptoms. Those that do may experience sharp, left-sided chest **pain**. Some complain of **fatigue** or a pounding feeling in the chest. Others can have an irregular heart beat and even pass out. Some persons may experience difficulty breathing, ankle swelling, and fluid in the lungs. Other symptoms may include **anxiety**, headaches, morning tiredness and constantly cold hands and feet. Death from this condition is rare.

Diagnosis

The diagnosis of MVP is based on symptoms and physical exam. During the exam, the physician may hear a click and/or heart murmur with a stethoscope.

WWW.BOOKBAZ.IR

KEY TERMS

Heart murmur—Sound during the heartbeat caused by a heart valve that does not close properly.

Rheumatic heart disease—A condition caused by a streptococcus infection which can result in permanent heart damage.

The best diagnostic test for MVP is the echocardiogram. The test reflects sound waves through the chest wall to give two-dimensional color flow pictures of the heart, its size, position, motion, chambers, and valves. Unfortunately, during the early 1980s, this diagnosis was often made excessively from faulty echocardiographic criteria prevalent at that time.

Any person with symptoms or family history of MVP should consider having an echocardiogram. The test takes 15-20 minutes and is done in doctor's offices and hospitals. It is performed by trained technicians and is read by cardiologists. Family physicians, internists, cardiologists, and nurse practitioners can treat MVP. Echocardiograms are recommended periodically depending on the extent of valve leakage.

Treatment

Persons who experience certain types of an irregular heartbeat with MVP should be treated. Propranolol (Inderal) or other **beta blockers** or **digoxin** (Lanoxin) are often helpful. Persons who develop moderate to severe symptoms with a leaky mitral valve may require repair or replacement of the mitral valve with an artificial heart valve. Persons with MVP and a leaky valve need to protect themselves from heart or heart valve infections. **Antibiotics** should be taken before any surgical, dental or oral procedures according to the American Heart Association recommendations.

Other treatments include drinking lots of fluids during strenuous activity and hot weather. Water pills, **caffeine** and donating blood may aggravate the symptoms of MVP.

Prognosis

MVP is usually not a serious condition. However, dangerous, untreated irregular heartbeats may rarely cause sudden death. These persons should be carefully monitored.

Lisa Papp, RN

Mitral valve stenosis

Definition

The term *stenosis* means an abnormal narrowing of an opening. Mitral valve stenosis refers to a condition in the heart in which one of the valve openings has become narrow and restricts the flow of blood from the upper left chamber (left atrium) to the lower left chamber (left ventricle).

Description

In the heart, the valve that regulates the flow of blood between the left atrium and the left ventricle is called the mitral valve. If the mitral valve is abnormally narrow, due to disease or birth defect, blood flow from the atrium to the ventricle is restricted. This restricted flow leads to an increase in the pressure of blood in the left atrium. Over a period of time, this back pressure causes fluid to leak into the lungs. It can also lead to an abnormal heart rhythm (**atrial fibrillation**), which further decreases the efficiency of the pumping action of the heart.

Causes and symptoms

Mitral valve stenosis is almost always caused by **rheumatic fever**. As a result of rheumatic **fever**, the leaflets that form the opening of the valve are partially fused together. Mitral valve stenosis can also be present at birth. Babies born with this problem usually require surgery if they are to survive. Sometimes, growths or tumors can block the mitral valve, mimicking mitral valve stenosis.

If the restriction is severe, the increased blood pressure can lead to **heart failure**. The first symptoms of heart failure, which are **fatigue** and **shortness of breath**, usually appear only during physical activity. As the condition gets worse, symptoms may also be felt even during rest. A person may also develop a deep red coloring in the cheeks.

Diagnosis

Mitral valve stenosis is usually detected by a physician listening to heart sounds. Normal heart

KEY TERMS

Atrium—One of the two upper chambers of the heart.

Beta blocker—A drug that can be used to reduce blood pressure.

Rheumatic fever—An illness which sometimes follows a streptococcal infection of the throat.

Ventricle—One of the two lower chambers of the heart.

valves open silently to permit the flow of blood. A stenotic valve makes a snapping sound followed by a "rumbling" murmur. The condition can be confirmed with a chest x ray and an electrocardiogram, both of which will show an enlarged atrium. **Echocardiography**, which produces images of the heart's structure, is also helpful in making the diagnosis. If surgery is necessary, **cardiac catheterization** may be done to fully evaluate the heart before the operation.

Treatment

Drug therapy may help to slow the heart rate, strengthen the heart beat, and control abnormal heart rhythm. Drugs such as **beta blockers**, **calcium channel blockers**, and **digoxin** may be prescribed. A drug that prevents abnormal blood clotting (anticoagulant) called warfarin (Coumadin) may be recommended. If drug therapy does not produce satisfactory results, valve repair or replacement may be necessary.

Repair can be accomplished in two ways. In the first method, **balloon valvuloplasty**, the doctor will try to stretch the valve opening by threading a thin tube (catheter) with a balloon tip through a vein and into the heart. Once the catheter is positioned in the valve, the balloon is inflated, separating the fused areas. The second method involves opening the heart and surgically separating the fused areas.

If the valve is damaged beyond repair, it can be replaced with a mechanical valve or one that is partly mechanical and partly made from a pig's heart.

Prognosis

Procedures available to treat mitral valve stenosis, whether medical or surgical, all produce effective results.

Prevention

The only possible way to prevent mitral valve stenosis is to prevent rheumatic fever. This can be done by evaluating sore throats for the presence of the bacteria that causes **strep throat**. Strep throat is easily treated with **antibiotics**.

Modified radical mastectomy

Definition

A modified radical **mastectomy** is a surgical procedure that removes the breast, surrounding tissue, and nearby lymph nodes affected by cancer.

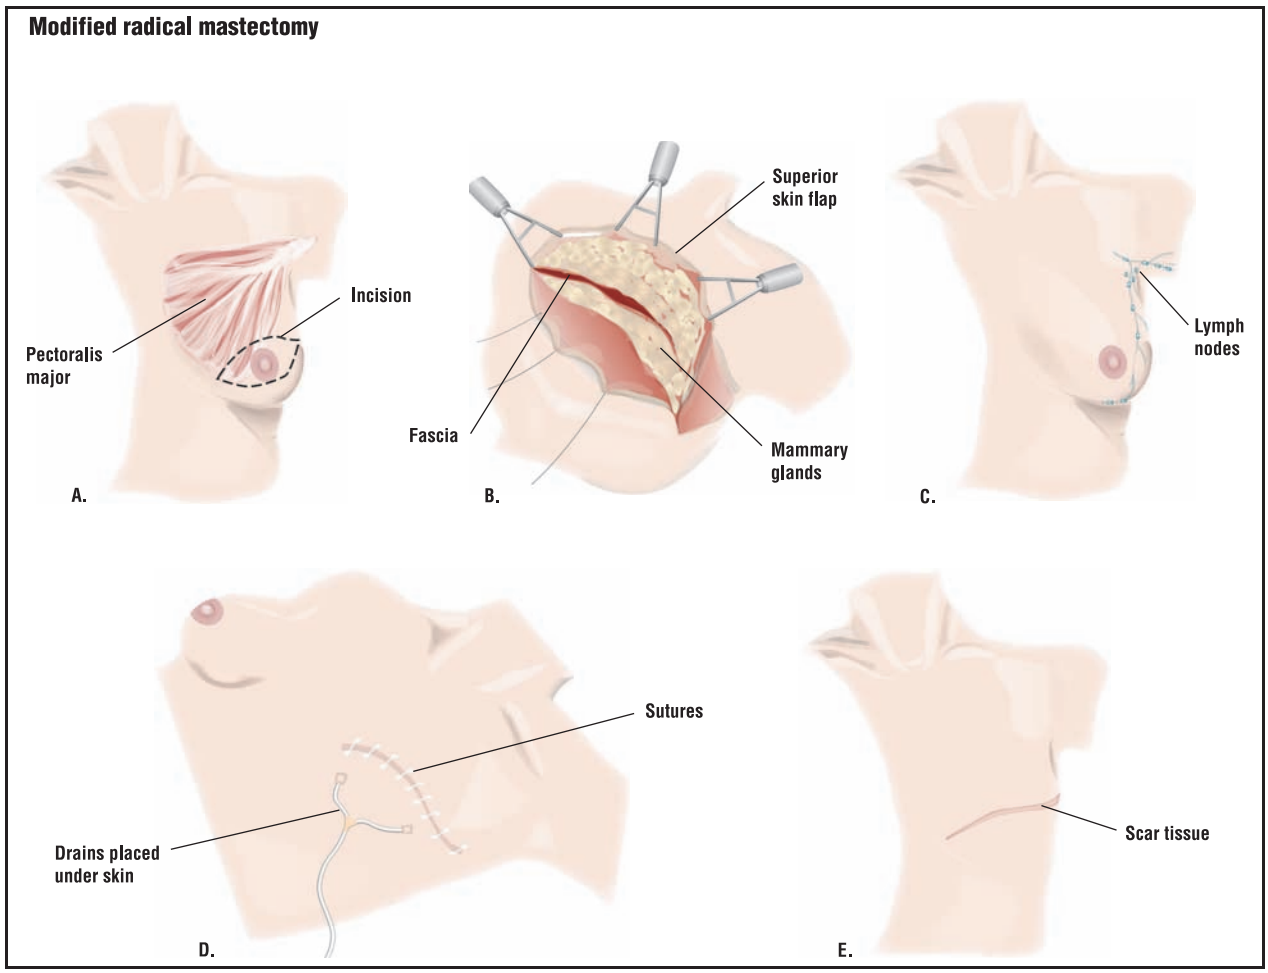
Purpose

The purpose of modified radical mastectomy is the removal of **breast cancer** (abnormal cells in the breast that grow rapidly and replace normal healthy tissue). Modified radical mastectomy is the most widely used surgical procedure to treat operable breast cancer. This procedure leaves a chest muscle called the pectoralis major intact. Leaving this muscle in place will provide a soft tissue covering over the chest wall and a normal-appearing junction of the shoulder with the anterior (front) chest wall. This sparing of the pectoralis major will avoid a disfiguring hollow defect below the clavicle. Additionally, the purpose of modified radical mastectomy is to allow for the option of **breast reconstruction**, a procedure that is possible, if desired, due to intact muscles around the shoulder of the affected side. The modified radical mastectomy procedure involves removal of large multiple tumor growths located underneath the nipple, as well as cancer cells on the breast margins.

Demographics

When all ages are taken into account, white women are more likely to contract breast cancer than other ethnicities, although in women under age 45,

WWW.BOOKBAZ.IR



In a modified radical mastectomy, the skin on the breast is cut open (A). The skin is pulled back, and the tumor, lymph nodes, and breast tissue are removed (B, C). The incision is closed (D). *(Illustration by GGS Information Services. Copyright © Cengage Learning®.)*

African American women have a higher risk of developing the disease. Additionally, African American women are more likely to die of the disease. The lowest risk of breast cancer development or death is in women of Asian, Hispanic, or Native American descent.

While considerably less common, men can also have breast cancer. According to the American Cancer Society, in 2013 there were approximately 2,240 new breast cancer diagnoses in men, with 410 deaths.

Known risk factors in women include a strong genetic correlation, with greatly increased risk among women with a close relative (mother, sister, maternal aunt, or maternal grandmother) who has had breast cancer. Increased susceptibility for development of breast cancer can occur in females who never breastfed a baby, had a child after age 30, started menstrual periods very early, or experienced **menopause** very late.

Breast cancer is the most common cancer in women, other than **skin cancer**. The American Cancer Society estimated that in 2013, 296,980 new cases of breast cancer were diagnosed in the United States, with 39,620 women dying as a result of the disease. Approximately one in eight women will develop breast cancer at some point in her life. The risk of developing breast cancer increases with age. Without even considering genetic and environmental factors, women aged 30 to 40 have a 1 in 252 chance of developing breast cancer, women aged 40 to 50 have a 1 in 68 chance, women aged 50 to 60 have a 1 in 35 chance, and women aged 60 to 70 have a 1 in 27 chance.

Description

The procedure is typically performed by a surgeon who has received five years of **general surgery** training and additional training in the specialty of

KEY TERMS

Lymphatic system—A system that filters excess tissue fluids through lymph nodes to return to the bloodstream.

surgical oncology. A surgeon who specializes in this field has expertise in removing cancerous tissues or areas. The procedure is performed in a hospital and requires that the hospital have a surgical care unit. In the surgical care unit, the patient will be treated by a team of professionals that includes, but is not limited to, physicians, nurses, physician assistants, and medical assistants.

The surgeon's goals during this procedure are to minimize any chance of local/regional recurrence, avoid any loss of function, and maximize options for breast reconstruction. Incisions are made to avoid visibility in a low-neckline dress or bathing suit. An incision in the shape of an ellipse is made. The surgeon removes the minimum amount of skin and tissue so that the remaining healthy tissue can be used for possible reconstruction. Skin flaps are made carefully and as thinly as possible to maximize removal of diseased breast tissues. The skin over a neighboring muscle (pectoralis major fascia) is removed, after which the surgeon focuses in the armpit (axillary) region. In this region, the surgeon carefully identifies vital anatomical structures such as blood vessels (veins, arteries) and nerves. Accidental injury to specific nerves like the medial pectoral neurovascular bundle will result in destruction of the muscles that this surgery attempts to preserve, such as the pectoralis major. In the armpit region, the surgeon carefully protects the vital structures while removing cancerous tissues. After axillary surgery, breast reconstruction can be performed if desired by the patient.

Diagnosis

Modified radical mastectomy is a surgical procedure to treat breast cancer. In order for this procedure to be an option, a definitive diagnosis of breast cancer must be established. The first clinical sign for approximately 80% of women with breast cancer is a mass (lump) located in the breast. A lump can be discovered by monthly self-examination or by a health professional who can find the 10%–25% of breast cancers that are missed by yearly mammograms (a low-radiation x-ray of the breasts). A biopsy can be performed to examine the cells from a lump that is suspicious for cancer. The diagnosis of the extent of the cancer and whether it has spread to regional lymph nodes determines the treatment course (i.e., whether to combat the cancer with surgery, **chemotherapy**, or **radiation therapy**, either singly or in combinations). Staging the cancer can estimate the amount of tumor, which is important not only for diagnosis but for prognosis (statistical outcome of the disease process). Patients with a type of breast cancer called ductal carcinoma in situ (DCIS), which is a stage 0 cancer, have the best outcome (nearly all these patients are cured of breast cancer). Persons whose cancer has spread to other places within the body (metastases) have stage IV cancer and the worst prognosis (potential for survival). At present, people affected with stage IV breast cancer have essentially no chance of cure.

Persons affected with breast cancer must undergo the staging of the cancer to determine the extent of cancerous growth and possible spread (metastasis) to distant organs. Patients with stage 0 disease have noninvasive cancer with a very good outcome. Stages I and II are early breast cancer without lymph node involvement (stage I) and with node-positive results (stage II). Persons with stage III cancer have locally advanced disease and about a 50% chance for five-year survival. Stage IV disease is the most severe, since the breast cancer cells have spread through lymph nodes to distant areas and/or other organs in the body. It is very unlikely that persons with stage IV metastatic breast cancer will survive 10 years after diagnosis.

It is also imperative to assess the degree of cancerous spread to lymph nodes within the armpit region. Of primary importance to stage determination and regional lymph node involvement is identification and analysis of the sentinel lymph node. The sentinel lymph node is the first lymph node to which any cancer would spread. The procedure for sentinel node biopsy involves injecting a radioactively labeled tracer (technetium 99) or a blue dye (isosulfan blue) into the tumor site. The tracer or dye will spread through the lymphatic system to the sentinel node, which should be surgically removed and examined for the presence of cancer cells. If the sentinel node and one or two other neighboring lymph nodes are negative, it is very likely that the remaining lymph nodes will not contain cancerous cells, and further surgery may not be necessary.

Once a breast lump (mass) has been identified by **mammography** or **physical examination**, the patient should undergo further evaluation to histologically (studying the cells) identify or rule out the presence

WWW.BOOKBAZ.IR

of cancer cells. A procedure called fine-needle aspiration allows the clinician to extract cells directly from the lump for further evaluation. If a diagnosis cannot be established by fine-needle biopsy, the surgeon should perform an open biopsy (surgical removal of the suspicious mass).

Preparation

Preparation for surgery is imperative. The patient should plan for both direct care and recovery time after modified radical mastectomy. Preparation immediately prior to surgery should include no food or drink after midnight before the procedure. Postsurgical preparation should include caregivers to help with daily tasks for several days.

Aftercare

After breast cancer surgery, women should undergo frequent testing to ensure early detection of cancer recurrence. It is recommended that mammograms, physical examinations, or additional tests (biopsies) be performed annually. Aftercare can also include **psychotherapy**, since mastectomy is emotionally traumatic. Affected women may be worried or have concerns about appearance, the relationship with their sexual partner, and possible physical limitations. Community-centered support groups usually made up of former breast cancer surgery patients can be a source of emotional support after surgery. Patients may stay in the hospital for one to two days. For about five to seven days after surgery, there will be one or two drains left inside the body to remove any extra fluid from the area after surgery. Usually, the surgeon will prescribe medication to prevent **pain**. Restrictions on movement should be specifically discussed with the surgeon.

Risks

There are several risks associated with modified radical mastectomy. The procedure is performed under general **anesthesia**, which itself carries risk. Women may have short-term pain and tenderness. The most frequent risk of breast cancer surgery (with extensive lymph node removal) is **edema**, or swelling of the arm, which is usually mild, but the presence of fluid can increase the risk of infection. Leaving some lymph nodes intact instead of removing all of them may help lessen the likelihood of swelling. Nerves in the area may be damaged. There may be numbness in the arm or difficulty moving shoulder muscles. There is also the risk of developing a lumpy scar (keloid) after surgery. Another risk is that the surgery did not remove all the cancer cells and that further treatment may be necessary (with chemotherapy and/or radiotherapy). By far, the worst risk is recurrence of cancer. However, immediate signs of risk following surgery include **fever**, redness in the incision area, unusual drainage from the incision, and increasing pain. If any of these signs develop, it is imperative to call the surgeon immediately.

Results

If no complications develop, the surgical area should completely heal within three to four weeks. After mastectomy, some women may undergo breast reconstruction (which can be done during mastectomy). Recent studies have indicated that women who undergo cosmetic **reconstructive surgery** have a higher quality of life and a better sense of well-being than those who do not utilize this option.

Morbidity and mortality rates

The outcome of breast cancer is very dependent on the stage at the time of diagnosis. The five-year survival rates for the various stages are:

- Stage 0, 93%
- Stage I (early/lymph node–negative), 88%
- Stage II (early/lymph node–positive), 74%–81%
- Stage III disease (locally advanced), 41%–67%
- Stage IV (metastatic), 15%

Approximately 17% of patients develop **lymphedema** after axillary lymph node dissection, while only 3% of patients develop lymphedema after sentinel node biopsy. Five percent of women are unhappy with the cosmetic effects of the surgery.

Alternatives

There are no effective alternatives to mastectomy. A mastectomy is recommended for tumors with dimensions over 2 in. (5 cm). Additional treatment (adjuvant) is typically recommended, with chemotherapy and/or radiation therapy administered to destroy any remaining cancer. Modified radical mastectomy is one of the standard treatment recommendations for stage III breast cancer.

Molar pregnancy *see* **Hydatidiform mole**

Moles

Definition

A mole (nevus) is a pigmented (colored) spot on the outer layer of the skin (epidermis).

Description

Moles can be round, oval, flat, or raised. They can occur singly or in clusters on any part of the body. Most moles are brown, but colors can range from pinkish flesh tones to yellow, dark blue, or black.

Demographics

Everyone has at least a few moles. They generally appear by the time a person is 20 and resemble freckles at first. A mole's color and shape don't usually change. Changes in hormone levels that occur during **puberty** and **pregnancy** can make moles larger and darker. New moles may also appear during this period.

A mole usually lasts about 50 years before beginning to fade. Some moles disappear completely, and some never lighten at all. Some moles develop stalks that raise them above the skin's surface; these moles eventually drop off.

Types of moles

About 1–3% of all babies have one or more moles when they are born. Moles that are present at birth are called congenital nevi.

Other types of moles include:

- Junctional moles, which are usually brown and may be flat or slightly raised
- Compound moles, which are slightly raised, range in color from tan to dark brown, and involve pigment-producing cells (melanocytes) in both the upper and lower layers of the skin (epidermis and dermis)
- Dermal moles, which range from flesh-color to brown, are elevated, most common on the upper body, and may contain hairs
- Sebaceous moles, which are produced by overactive oil glands and are yellow and rough-textured
- Blue moles, which are slightly raised, colored by pigment deep within the skin, and most common on the head, neck, and arms of women

Most moles are benign, but atypical moles (dysplastic nevi) may develop into malignant **melanoma**, a potentially fatal form of **skin cancer**. Atypical moles are usually hereditary. Most are bigger than a pencil eraser, and the shape and pigmentation are irregular.

Congenital nevi are more apt to become cancerous than moles that develop after birth, especially if they are more than eight inches in diameter. Lentigo maligna (melanotic freckle of Hutchinson), most common on the face and after the age of 50, first appears as a flat spot containing two or more shades of tan. It gradually becomes larger and darker. One in three of these moles develop into a form of skin cancer known as lentigo maligna melanoma.

WWW.BOOKBAZ.IR

Woman's birthmark being removed by laser. *(Alexander Tsiaras/Photo Researchers, Inc.)*

Causes and symptoms

The cause of moles is unknown, although atypical moles seem to run in families and result from exposure to sunlight.

In the past several years, researchers have identified two genes known as CDKN2A and CDK4 that govern susceptibility to melanoma in humans. Most experts, however, think that these susceptibility genes are not sufficient by themselves to account for moles becoming cancerous but are influenced by a combination of other inherited traits and environmental factors.

Diagnosis

Only a small percentage of moles require medical attention. A mole that has the following symptoms should be evaluated by a dermatologist (a physician spealizing in skin diseases).

- Appears after the age of 20
- Bleeds
- Itches
- Looks unusual or changes in any way.

A doctor who suspects skin cancer will remove all or part of the mole for microscopic examination. This procedure, which is usually performed in a doctor's office, is simple, relatively painless, and does not take more than a few minutes. It does leave a scar.

The doctor may also use a dermatoscope to examine the mole prior to removal. The dermatoscope, which can be used to distinguish between benign moles and melanomas, is an instrument that resembles an ophthalmoscope. An immersion oil is first applied to the mole to make the outer layers of skin transparent.

A combination of high-frequency **ultrasound** and color Doppler studies has also been shown to have a high degree of accuracy in distinguishing between melanomas and benign moles.

Treatment

If laboratory analysis confirms that a mole is cancerous, the dermatologist will remove the rest of the mole. Patients should realize that slicing off a section of a malignant mole will not cause the cancer to spread.

KEY TERMS

Dermatology—The branch of medicine that studies and treats disorders of the skin.

Malignant melanoma—A potentially fatal form of skin cancer that develops from melanocytes, which are skin cells containing melanin.

Melanin—A dark insoluble pigment found in humans in the skin, hair, choroid layer of the eye, and a part of the brain called the substantia nigra.

Nevus (plural, nevi)—The medical term for any anomaly of the skin that is present at birth, including moles and birthmarks.

Removing a mole for cosmetic reasons involves numbing the area and using scissors or a scalpel to remove the elevated portion. The patient is left with a flat mole the same color as the original growth. Cutting out parts of the mole above and beneath the surface of the skin can leave a scar more noticeable than the mole.

Cryotherapy may also be used to remove moles. In cryotherapy, the physician uses an extremely cold liquid to freeze and destroy the skin growth.

Scissors or a razor can be used to temporarily remove hair from a mole. Permanent hair removal, however, requires electrolysis or surgical removal of the mole.

Prognosis

Moles are rarely cancerous and, once removed, unlikely to recur. A dermatologist should be consulted if a mole reappears after being removed.

Prevention

Wearing a sunscreen and limiting sun exposure may prevent some moles. Anyone who has moles should examine them every month and see a dermatologist if changes in size, shape, color, or texture occur or if new moles appear.

A team of researchers at Duke University reported in 2003 that topical application of a combination of 15% vitamin C and 1% **vitamin E** over a four-day period offered significant protection against **sunburn**. The researchers suggest that this combination may protect skin against **aging** caused by sunlight as well.

Anyone with a family history of melanoma should see a dermatologist for an annual skin examination. Everyone should know the ABCDEs of melanoma:

- A: Asymmetry, which occurs when the two halves of the mole are not identical
- B: Borders that are irregular or indistinct
- C: Color that varies in a single mole
- D: Diameter, which should be no larger than a pencil eraser (about 6 mm)
- E: Elevated above the surrounding tissue.

A mole with any of these characteristics should be evaluated by a dermatologist.

Advances in photographic technique have now made it easier to track the development of moles with the help of whole-body photographs. A growing number of hospitals are offering these photographs as part of outpatient mole-monitoring services.

Monkeypox

Definition

Monkeypox is an **infectious disease** caused by an orthopoxvirus. Orthopoxviruses are a genus of viruses that include the disease agents that cause human **smallpox**, cowpox, and camelpox as well as monkeypox. Monkeypox, which was first identified in humans in an outbreak in Africa in 1970, usually produces a less severe illness with fewer fatalities than smallpox. However, its symptoms are similar: **fever**, pus-filled blisters all over the body, and respiratory problems.

Monkeypox is classified as a **zoonosis**, which means that it is a disease of animals that can be transmitted to humans under natural conditions. The first cases of monkeypox reported in humans involved contact between humans and animals in the African rain forest. The outbreak that made headlines in the United States in June 2003, however, involved animals purchased as pets from pet stores. In nature, monkeypox has been found in monkeys, chimpanzees, rabbits, prairie dogs, Gambian rats, ground squirrels, and mice. It was not known as of late 2003 whether other wild or domestic animals can contract monkeypox.

Description

Prior to 2003, most monkeypox cases were diagnosed in remote areas of central and west Africa. Between February 1996 and October 1997, however, there were 511 suspected cases of monkeypox in the Democratic Republic of the Congo (DRC, formerly Zaire). This outbreak, the largest ever, raised fears that the virus had mutated and become more infectious.

In late 1997, the U.S. Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) announced that this relatively large outbreak was likely due to human behavior, rather than virus mutation. During the outbreak, the DRC was embroiled in civil war. Food shortages increased reliance on hunting and raised chances that people would come into contact with infected animals.

The 2003 outbreak in the United States, which was the first confirmed instance of community-acquired monkeypox in North America, came to the attention of the CDC in early June, when a laboratory in Wisconsin identified the monkeypox virus in samples taken from the skin of an infected patient and lymph node tissue from the patient's pet prairie dog. By the end of June, cases of monkeypox in humans had been identified in six Midwestern states (Illinois, Indiana, Kansas, Missouri, Ohio, and Wisconsin). The patients acquired the virus from infected prairie dogs purchased as pets, which in turn were infected through contact with animals imported from Africa that were sold in the same pet stores.

Monkeypox is less severe than smallpox and can sometimes be confused with **chickenpox**. It seems partly preventable with smallpox **vaccination**, but vaccination programs were discontinued in the late 1970s. (Barring samples stored in laboratories, smallpox has been eradicated.) People under the age of 16—those born after smallpox vaccination ended—seem the most susceptible to monkeypox. During the 1996-97 outbreak, approximately 85% of the cases were in this age group.

Although the monkeypox virus is related to the smallpox virus, experts do not think that it is likely to be cultivated as an agent of bioterrorism. Monkeypox is much less easily transmitted person-to-person than smallpox and has a much lower fatality rate.

Causes and symptoms

The monkeypox virus is transmitted to humans through an infected animal's blood, body sores, or bite or through handling an infected animal's bedding or cage. Initial symptoms of monkeypox in humans include fever, a bodywide rash (exanthem) of pus-filled blisters, and flu-like muscle aches and **fatigue**. These symptoms can be accompanied by **diarrhea**, swollen lymph nodes, a **sore throat**, and mouth sores. In some cases, a victim may experience trouble breathing. Symptoms are at their worst for 3–7 days, after which the fever lessens and blisters begin to form crusts.

The symptoms of monkeypox in pet rabbits, rats, or mice include inflammation of the eyes, a nasal discharge, fever, loss of appetite, a skin rash, and tiredness. Pet monkeys typically develop a rash with pus-filled lesions on the palms of the hands, trunk, and tail. They may also have mouth **ulcers**.

Diagnosis

Since the symptoms of monkeypox resemble other diseases caused by orthopox viruses, definitive diagnosis may require laboratory testing to uncover the virus or evidence (from antibodies in the blood) that it is present. Laboratory techniques that can be used to identify the monkeypox virus include electron microscopy, polymerase chain reaction (PCR), immunohistochemistry, and ELISA testing.

KEY TERMS

Antiviral—Refers to a drug that can destroy viruses and help treat illnesses caused by them.

Bioterrorism—The intentional use of disease-causing microbes or other biologic agents to intimidate or terrorize a civilian population for political or military reasons.

Mutation—A change in an organism's genetic code that causes it to develop new characteristics.

Orthopoxvirus—The genus of viruses that includes monkeypox, smallpox, cowpox, and camelpox.

Symptomatic—Refers to treatment that addresses the symptoms of an illness, but not its underlying cause.

Zoonosis (plural, zoonoses)—Any disease of animals that can be transmitted to humans under natural conditions. Monkeypox is a zoonosis.

Treatment

Like most viruses, monkeypox cannot be resolved with medication. The only treatment option is symptomatic—that is, patients are made as comfortable as possible. In March 1998, the U.S. Army Medical Research Institute for Infectious Diseases reported that an antiviral drug called cidofovir may combat monkeypox infection. Additional studies report that cidofovir appears to be safe and effective as a treatment for monkeypox in humans.The drug has worked successfully in primates, but further research is needed to determine its effectiveness in humans.

Prognosis

Children are more likely to contract the disease and have the highest death rate. Monkeypox is not as lethal as smallpox, but the death rate among young children may reach 2–10%. In some cases, hospitalization is required. Recovery is good among survivors, although some scarring may result from the blisters.

Prevention

Monkeypox is one of the diseases that physicians, veterinarians, and **public health** officials are required by law to report to the CDC.

Although smallpox vaccination offers some protection against monkeypox, experts do not generally recommend getting a smallpox vaccination simply to guard against monkeypox if one has not been exposed to it. However, the CDC recommends as of June 2003 that anyone who has had close contact with humans or animals infected with monkeypox, or has helped to care for them, should be vaccinated against smallpox. The vaccination can be administered as late as 14 days after exposure to the virus. In addition, veterinarians or public health personnel conducting field investigations should be vaccinated before any exposure to monkeypox.

As of late 2003, no cases of monkeypox were identified in cats or dogs belonging to people infected by the June outbreak. The American Veterinary Medicine Association (AVMA) recommends, however, that cats, dogs, or other mammals that have been in contact with an animal known to have monkeypox should be kept in quarantine for 30 days from the date of exposure.

People who have a pet with symptoms of monkeypox should *not* take it to an animal shelter or release it into the wild. They should isolate it from humans and other animals, and take it to a veterinarian in a closed, chew-proof container with air holes.

On June 11, 2003, the CDC and the Food and Drug Administration (FDA) issued a joint order prohibiting the importation of rats and other rodents from Africa. In addition, the agencies banned the sale and distribution of prairie dogs and six species of African rodents in the United States.

Monoamine oxidase inhibitors

Definition

Monoamine oxidase inhibitors (MAOI) are medicines used to treat severe mental depression.

Purpose

Like other **antidepressant drugs**, MAOI help reduce the sadness, hopelessness, apathy and lack of interest in life that are typical of depression. In use since the 1950s, these drugs are associated with greater risks of interactions with foods and other drugs than other types of antidepressants, and are generally reserved for cases where other drugs are not effective.

Description

MAOI work by correcting chemical imbalances in the brain. Normally, chemicals, called neurotransmitters, carry signals between brain cells. Some neurotransmitters, such as serotonin and norepinephrine, play important roles in controlling mood. MAOI are believed to block or reduce the breakdown of serotonin and norepinephrine, prolonging and increasing their effects.

MAOI are available only with a physician's prescription. Examples include isocarboxazid (Marplan), phenelzine (Nardil), tranylcypromine (Parnate), available as tablets; and selegiline (Emsam), available as a skin patch.

Recommended dosage

Dosage depends on the type of MAOI prescribed, the type of depression treated, and characteristics of individual patients. Prescribers or pharmacists can advise on correct dosage and use.

Always take MAOI exactly as directed. These drugs may take up to several weeks to be effective. Do not stop taking them suddenly, as withdrawal symptoms may occur. Prescribers should advise and monitor reducing or discontinuing these drugs.

MAOI may be taken with or without food, or on an empty stomach. Some foods and beverages must be avoided while taking these drugs.

Precautions

All types of antidepressant medications increase the risk of **suicide** in children, adolescents, and young adults.

These drugs may worsen **psychosis**, and should not be used alone to treat **bipolar disorder**.

Diabetics using insulin may experience more low blood sugars when they take MAOI

MAOI may cause serious and possibly life-threatening high blood pressure within several hours after eating certain foods like aged cheeses, smoked or pickled meats, chocolate, foods containing monosodium glutamate (MSG), or drinking red wine or caffeinated beverages. Before started on these drugs, a full list of foods and beverages to be avoided should be obtained from a physician or pharmacist.

The effects and interactions of these drugs with food, beverages and other drugs may continue for up to two weeks after they are discontinued.

MAOI should be discontinued at least two weeks before **anesthesia** or elective surgery or dental procedures where local anesthetics containing epinephrine might be used.

These drugs may produce dangerously high blood pressure in people who take **central nervous system**

stimulants to treat **attention deficit hyperactivity disorder (ADHD)**.

When taken with **central nervous system depressants**, like cyclobenzaprine (Flexeril), meperidine (Demerol), bupropion (Wellbutrin), and buspirone (Buspar), **delirium**, excitement, **coma**, seizures, or high **fever** may occur.

At least five weeks should elapse after discontinuing **selective serotonin reuptake inhibitors** (SSRIs), like Prozac, before beginning treatment with MAOI.

Anyone who is taking MAOIs should not use medicines that have not been approved or prescribed by physicians familiar with these drugs. This includes over-the-counter medicines like sleep aids; colds, coughs, hay fever, or **asthma** medications, including nose drops or sprays containing neosynephrine or pseudoephedrine; medicines to increase alertness or keep from falling asleep, like NoDoz; and appetite control products.

MAOI may cause blurred vision or make people feel drowsy, dizzy or lightheaded. Anyone taking these drugs should not drive, use machines or do other potentially dangerous activities until they are familiar with the drugs's effects.

The elderly may be more sensitive to the effects of MAOI.

Special conditions

People with certain medical conditions or who are taking certain other medicines can have problems if they take MAOI. Before taking these drugs, people should be be sure to let their physician know about any of these conditions:

ALLERGIES. Anyone who has had unusual reactions to MAOI in the past should let his or her physician know before taking them again. Physicians should be told about **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. MAOI may increase the risks of **birth defects** or problems in newborns. Women who are, or may become, pregnant should discuss these issues with their physicians before taking a MAOI.

BREASTFEEDING. MAOI pass into breast milk and are not recommended for nursing mothers unless the expected benefits outweigh the risks.

DIABETES. Diabetics using insulin and/or oral drugs to control blood sugar should be aware that MAOI increase sensitivity to these drugs.

ANGINA. People with **angina** (chest **pain**) may feel more energetic while taking MAOI and should be careful not to overexert themselves.

OTHER MEDICAL CONDITIONS. Before using MAOI, people with any of these medical problems should make sure their physicians are aware of their conditions:

- Alcohol abuse
- High blood pressure
- Recent heart attack or stroke
- Heart or blood vessel disease
- Liver disease
- Kidney disease
- Frequent or severe headaches
- Epilepsy
- Parkinson's disease
- Current or past mental illness
- Asthma or bronchitis
- Overactive thyroid
- Pheochromocytoma (a tumor of the adrenal gland)

USE OF CERTAIN MEDICINES. Taking MAOI with certain other drugs may affect the way the drugs work and increase the risk of side/adverse effects.

Side effects

The most common side effects include **dizziness**, lightheadedness, drowsiness, weakness, blurred vision, shakiness or trembling, restlessness, sleep problems or twitching during sleep, weight gain, decreased sexual ability, difficulty with urination, and **headache**. These problems usually go away as the body adjusts to the drug and do not require medical treatment unless they interfere with normal activities.

Serious side/averse effects may occur. If any of the following occur seek emergency medical attention:

- Severe chest pain
- Severe headache
- Stiff, sore neck
- Enlarged pupils
- Hypersensitivity to light
- Rapid or slow heartbeat
- Sweating, with or without fever or cold, clammy skin
- Nausea and vomiting

Other side effects may occur. Anyone who has unusual or troublesome symptoms while taking MAOI should contact their physician.

Interactions

MAOI interact with many other medicines, changing the effects of one or both drugs and changing the risks of side/adverse effects. *People taking*

WWW.BOOKBAZ.IR

KEY TERMS

Anxiety—Apprehension in response to real or imagined stress, danger, or dreaded situations. Physical symptoms like rapid pulse, sweating, trembling, fatigue, and weakness may accompany anxiety.

Central nervous system—The brain and spinal cord.

Depression—A mental condition where people feel extremely sad and lose interest in life. People with depression may also have sleep problems and loss of appetite and may have trouble concentrating and carrying out everyday activities.

Neurotransmitters—Chemicals that carry impulses, messages, between nerve cells.

Phobia—Intense, illogical fear of specific conditions like heights, crowds or open spaces.

Withdrawal symptoms—Physical and/or mental symptoms that occur when people stop using drugs to which they have become physically or psychologically dependent.

MAOI must check with their physicians before taking other prescription or nonprescription (over-the-counter) medicines. Drugs that interact with MAO inhibitors include:

- Central nervous system (CNS) depressants, stimulants, over the counter medicines for allergies, colds, hay fever, sleep and asthma; sedatives; tranquilizers; prescription pain medicines; muscle relaxants; antiseizure medicines; barbiturates; and anesthetics
- Medicine for high blood pressure
- Other antidepressants, including tricyclic antidepressants (such as Tofranil and Norpramin), antidepressants that raise serotonin levels (such as Prozac and Zoloft), and bupropion (Wellbutrin)
- Insulin and diabetes medicines taken by mouth
- Water pills (diuretics)

The list above does not include every drug that may interact with MAOI. Check with a physician or pharmacist before combining MAOI with any other prescription or nonprescription (over-the-counter) medicine.

Nancy Ross-Flanigan

Monoclonal antibodies

Definition

Monoclonal antibodies (MAb) are identical, laboratory-produced antibodies made from mice that have been genetically engineered in such a way as to produce human and human-like antibodies.

Purpose

As of 2014, more than three dozen monoclonal antibodies were used to treat certain cancers, autoimmune diseases such as **rheumatoid arthritis**, and transplant rejection reactions. Of these, about nine are fully human monoclonal antibodies.

Description

Antibodies are proteins that the immune system makes in response to foreign material in the body. Monoclonal antibodies are antibodies made from a single type of cell type. They are all identical. Each type of antibody is made in response to a specific antigen. This specificity is what makes them such a desirable therapy. While **chemotherapy** agents and radiation kill many types of cells, MAbs target only cells with a specific type of protein on their surface. This allows abnormal cells to be killed while normal cells remain largely intact.

There are four different types of monoclonal antibodies. Murine MAb are made from mouse cells. They were the first type of monoclonal antibody to be developed. The first murine MAb was a transplant rejection drug approved by United States Food and Drug Administration (FDA) in 1986. The problem with murine MAbs was that they had a short life in the body. Human immune system cells recognized murine MAbs as foreign and rapidly destroyed them. The generic (non-brand) names of all murine monoclonal antibodies end in the suffix *-omab*.

To help overcome the body's reaction to murine MAbs, researchers develop what are called chimeric MAbs. These MAbs were created by fusing mouse gene sequences on to human gene sequences. Chimeric MAbs produced less reaction by the human immune system and remained longer in the body. Generic chimeric MAbs end in the suffix *-ximb*.

The third type of MAbs are called humanized MAbs. Humanized antibodies are about 95% of human origin; the remaining material is mouse DNA. Although the human body accepts humanized MAbs better than murine or chimeric MAbs, there are drawbacks in the effectiveness of the antibody binding

to the antigen on the cell it is intended to attack. The generic names of humanized MAbs all end in the suffix *-zumab*.

Fully human MAbs are produced through genetic engineering to create transgenic mice. Human immunoglobulin genes responsible for making a specific antibody are transferred into the genome of the mouse. The mouse is then injected with the antigen that stimulates production of the desired antibody. The human immunoglobulin genes produce human antibodies against the antigen in the mouse.These can then be harvested from mouse blood and grown in the laboratory. The generic names of fully human MAbs all end in the suffix *-umab*.

How MAbs work

All MAbs are designed to recognize and lock on to a specific protein on the surface of the target cell, but after that, they can function in different ways.

- Some MAbs trigger the immune system to attack cancer cells. Cancer cells are abnormal variations of normal cells. This can make them hard for the body's immune system to identify them, since a healthy immune system does not attack the body's own cells. Some MAbs attach themselves to cancer cells, making them look more abnormal and easier for the body's immune system cells to identify and destroy. Examples of MAbs that work this way are rituximab (a chimeric MAb) used to treat non-Hodgkin lymphoma and some types of and leukemia and alemtuzumab (a humanized MAb) used to treat chronic lymphocytic leukemia.
- Some MAbs attach themselves to normal human immune system cells called T-cells. T-cells help kill cancer cells and other abnormal cells. The surface protein the MAb attaches itself to normally tells the T-cell when to stop dividing. The MAb blocks this protein, so that the T-cell divides far more often than it normally would. Producing more T-cells boosts the immune system. Ipilmumab (a fully human MAb) works this way and is very effective against melanoma, an aggressive form of skin cancer.
- Other MAbs latch on to growth factor receptors on the surface of abnormal cells. They block the growth factor protein from interacting with the growth factor receptor. This prevents the cell from dividing. Examples of MAb that work this way include trastuzumab (humanized MAb) used to treat breast cancer, bevacizumab (humanized MAb), approved for treatment of colorectal cancer, and sometimes used off-label to treat age-related macular degeneration, cetuximab (fully human MAb), used to treat colorectal cancer and in trials to treat other cancers, and panitumumab (fully human MAb) used to treat colorectal cancer.
- MAbs can also be engineered to have radioactive substances or cell-killing drugs attached to them. This allows the delivery of radiation or a drug directly to the cell, killing it but leaving other cells relatively unharmed. Examples of MAbs that deliver radioactivity are ibritiumomab and tositumomab, both murine and both used to treat non-Hodgkin lymphoma. Gemtuzumab (humanized MAb) is used to deliver a drug for the treatment of acute leukemia.

KEY TERMS

Antibodies—Proteins normally produced by the immune system to fight infection or rid the body of foreign material. The material that stimulates the production of antibodies is called an antigen. Specific antibodies are produced in response to each different antigen and can only inactivate that particular antigen.

Antigen—Any foreign substance, usually a protein, that stimulates the body's immune system to produce antibodies.

Humanize—Fusing the constant and variable framework region of one or more human immunoglobulins with the binding region of an animal immunoglobulin, done to reduce human reaction against the fusion antibody.

Immune response—Physiological response of the body controlled by the immune system that involves the production of antibodies to fight off specific foreign substances or agents (antigens).

Immune system—The mechanism that protects the body from foreign substances, foreign cells, and pathogens. The thymus, spleen, lymph nodes, white blood cells, including the B cells and T cells, and antibodies are involved in the immune response, which aims to destroy these foreign materials that has entered the body.

Monoclonal—Genetically engineered antibodies that are all identical and specific for one antigen.

Off-label use—Use of a drug for other than the FDA approved purpose. It is legal for physicians to administer drugs for off-label uses, but pharmaceutical companies cannot advertise drugs for such uses.

WWW.BOOKBAZ.IR

Recommended dosage

MAbs are administered intravenously by slow-drip infusion. Often drugs are given before administration of the Mab to reduce side effects. The recommended dosage varies with the type of MAb, the disease that it is treating, response to treatment, and other drugs the patient is taking.

Precautions

MAbs pass across the placenta and into breast milk, so they should not be given to pregnant or nursing women.

MAb therapy is extremely expensive. Individuals should check with their insurance carrier to make sure these drugs are covered under their policy. Some MAbs are considered experimental or off-label use and may not be covered.

Many MAbs are under development and in clinical trials. A searchable database of FDA-approved clinical trials can be found at https://clinicaltrials.gov. Participation in clinical trials is always voluntary and at no cost to the patient.

Side effects

Side effects vary somewhat with the type of MAb administered, but some common, but generally moderate, side effects of all MAbs include:

- hives or itching
- chills or fever
- fatigue
- muscle aches
- nausea and vomiting
- diarrhea
- skin rashes

Serious, but less common, side effects include:

- infusion reaction that resemble allergic reactions and can lead to death
- low blood cell counts
- cardiovascular problems including rarely heart attack and heart failure
- excessive bleeding

Interactions

MAbs are relatively new drugs. **Drug interactions** will vary depending on the type of MAb. Since many drug interactions have not been well studied, it is best if patients ask the prescribing physician for the most up-to-date information on interactions.

Mood disorders

Definition

Mood disorders are mental disorders characterized by periods of depression, sometimes alternating with periods of elevated mood.

Description

While many people go through sad or elated moods from time to time, people with mood disorders suffer from severe or prolonged mood states that disrupt their daily functioning. Among the general mood disorders classified in the fourth edition (1994) of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM–IV*) are major depressive disorder, **bipolar disorder**, and dysthymia.

In classifying and diagnosing mood disorders, doctors determine if the mood disorder is unipolar or bipolar. When only one extreme in mood (the depressed state) is experienced, this type of depression is called unipolar. Major depression refers to a single severe period of depression, marked by negative or

hopeless thoughts and physical symptoms like **fatigue**. In major depressive disorder, some patients have isolated episodes of depression. Between these episodes, the patient does not feel depressed or have other symptoms associated with depression. Other patients have more frequent episodes.

Bipolar depression or bipolar disorder (sometimes called manic depression) refers to a condition in which people experience two extremes in mood. They alternate between depression (the "low" mood) and **mania** or hypomania (the "high" mood). These patients go from depression to a frenzied, abnormal elevation in mood. Mania and hypomania are similar, but mania is usually more severe and debilitating to the patient.

Dysthymia is a recurrent or lengthy depression that may last a lifetime. It is similar to major depressive disorder, but dysthymia is chronic, long-lasting, persistent, and mild. Patients may have symptoms that are not as severe as major depression, but the symptoms last for many years. It seems that a mild form of the depression is always present. In some cases, people also may experience a major depressive episode in addition to their dysthymia, a condition sometimes referred to as a "double depression."

Causes and symptoms

Mood disorders tend to run in families. These disorders are associated with imbalances in certain chemicals that carry signals between brain cells (neurotransmitters). These chemicals include serotonin, norepinephrine, and dopamine. Women are more vulnerable to unipolar depression than are men. Major life stressors (such as divorce, serious financial problems, and death of a family member) often provoke the symptoms of depression in susceptible people.

Major depression is more serious than just feeling "sad" or "blue." The symptoms of major depression may include:

- Loss of appetite
- A change in sleep patterns, such as not sleeping (insomnia) or sleeping too much
- Feelings of worthlessness, hopelessness, or inappropriate guilt
- Fatigue
- Difficulty in concentrating or making decisions
- Overwhelming and intense feelings of sadness or grief
- Disturbed thinking.
- The person may also have physical symptoms such as stomachaches or headaches

Bipolar disorder includes mania or hypomania. Mania is an abnormal elevation in mood. The person may be excessively cheerful, have grandiose ideas, and may sleep less. He or she may talk nonstop for hours, have unending enthusiasm, and demonstrate poor judgement. Sometimes the elevation in mood is marked by irritability and hostility rather than cheerfulness. While the person may at first seem normal with an increase in energy, others who know the person well see a marked difference in behavior. These patients may seem to be in a frenzy and often will make poor, bizarre, or dangerous choices in their personal and professional lives. Hypomania is not as severe as mania and does not cause the level of impairment in work and social activities that mania can.

Diagnosis

Doctors diagnose mood disorders based on the patient's description of the symptoms as well as the patient's family history. The length of time the patient has had symptoms also is important. Generally patients are diagnosed with dysthymia if they feel depressed more days than not for at least two years. The depression is mild but long lasting. In major depressive disorder, the patient is depressed almost all day nearly every day of the week for at least two weeks. The depression is severe. Sometimes laboratory tests are performed to rule out other causes for the symptoms (such as thyroid disease). The diagnosis may be confirmed when a patient responds well to medication.

Treatment

The most effective treatment for mood disorders is a combination of medication and **psychotherapy**. Individuals may have better results if they also participate in family-focused therapy. The four different classes of drugs used in mood disorders are:

- Heterocyclic antidepressants (HCAs), such as amitriptyline (Elavil)
- Selective serotonin reuptake inhibitors (SSRI inhibitors), such as fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft)
- Monoamine oxidase inhibitors (MAOI inhibitors), such as phenelzine sulfate (Nardil) and tranylcypromine sulfate (Parnate)
- Mood stabilizers, such as lithium carbonate (Eskalith) and valproate, often used in people with bipolar mood disorders.

A number of psychotherapy approaches are useful as well. Interpersonal psychotherapy helps the patient recognize the interaction between the mood

WWW.BOOKBAZ.IR

KEY TERMS

Cognitive therapy—Psychotherapy technique designed to help people change their attitudes, perceptions, and patterns of thinking.

Electroconvulsive therapy (ECT)—Therapy for mood disorders that involves passing electrical current through the brain in order to create a brief convulsion.

Neurotransmitter—A chemical that aids or alters the transmission of impulses between the points that connect nerves.

Serotonin—A chemical messenger in the brain thought to play a role in mood regulation.

disorder and interpersonal relationships. Cognitive–behavioral therapy explores how the patient's view of the world may be affecting his or her mood and outlook.

When depression fails to respond to treatment or when there is a high risk of **suicide**, **electroconvulsive therapy** (ECT) sometimes is used. ECT is believed to affect neurotransmitters as medications do. Patients are anesthetized and given **muscle relaxants** to minimize discomfort. Then low–level electric current is passed through the brain to cause a brief convulsion. The most common side effect of ECT is mild, short–term **memory loss**.

Alternatives

There are many alternative therapies that may help in the treatment of mood disorders, including **acupuncture**, botanical medicine, homeopathy, **aromatherapy**, constitutional **hydrotherapy**, and **light therapy**. The therapy used is an individual choice. Short–term clinical studies have shown that the herb St. John's wort (*Hypericum perforatum*) can effectively treat some types of depression. Though it appears very safe, the herb may have some side effects and its long–term effectiveness has not been proven. It has not been tested in patients with bipolar disorder. Despite uncertainty concerning its effectiveness, a 2003 report said acceptance of the treatment continued to increase. A poll showed that about 41% of 15,000 science professionals in 62 countries said they would use St. John's wort for mild to moderate depression. Although St. John's wort appears to be a safe alternative to conventional antidepressants, care should be taken, as the herb can interfere with the actions of some pharmaceuticals. The usual dose is 300 mg three times daily. St. John's wort and **antidepressant drugs** should not be taken simultaneously, so patients should tell their doctor if they are taking St. John's wort.

Prognosis

Most cases of mood disorders can be successfully managed if properly diagnosed and treated.

Prevention

People can take steps to improve mild depression and keep it from becoming worse. They can learn **stress** management (such as relaxation training or breathing exercises), **exercise** regularly, and avoid drugs or alcohol.

Mosquito-borne disease

Definition

Mosquito-borne diseases are a group of viral and parasitic diseases carried by mosquitoes as vectors. They are classified as zoonoses or zoonotic diseases because they are transmitted from animals to humans. These diseases are a source of widespread illness and death among animals as well as humans; and it is estimated that over a million people worldwide die each year from these illnesses. Originally limited to the warmer regions of the globe, mosquito-borne infections have been carried to all countries as a result of urbanization, population growth, and increased international travel. The only continent that is completely free of mosquitoes is Antarctica. The English word *mosquito* comes from the Portuguese and means "little fly."

There are about 3,500 known species of mosquitoes worldwide, with about 200 different species found in the United States and Canada. Not all mosquitoes transmit disease: The most dangerous genera of mosquitoes are *Culex*, which carries **West Nile virus**, **Japanese encephalitis**, and St. Louis encephalitis; *Culiseta*, which carries Western equine encephalitis; *Anopheles*, which carries the **malaria** parasite; and *Aedes*, responsible for transmitting **yellow fever**, dengue, and **chikungunya**.

Description

Mosquito-borne diseases can be divided into viral and parasitic diseases for purposes of description.

Arboviral mosquito-borne diseases

Arboviruses are a group of mosquito-borne viruses that cause encephalitis (inflammation of the brain) along with other symptoms. These diseases include:

- Eastern equine encephalitis (EEE): EEE is primarily a disease of horses, as its name indicates. About 220 cases of EEE in humans were confirmed between 1964 and 2004, primarily in swamplands in Florida, Massachusetts, New Jersey, and Georgia. The risk of EEE is highest along the East Coast, the Gulf Coast, and the Great Lakes. It is transmitted by *Culex* mosquitoes. Symptoms in humans may range from none at all to a mild flu-like illness with fever, headache, and sore throat. More serious infections of the central nervous system can lead to a sudden fever and severe headache followed quickly by seizures and coma; about half of patients with CNS involvement die.
- Japanese encephalitis (JE): Japanese encephalitis is a vaccine-preventable arboviral disease spread by mosquitoes in Asia and the western Pacific region, typically areas with intensive rice farming. It is most common during the rainy season. Most people infected with JE have no symptoms or only a mild flu-like illness. In severe cases, fever, chills, headache, fatigue, nausea and vomiting indicate the presence of encephalitis. The patient may progress to seizures, coma, or paralysis.
- La Crosse encephalitis (LAC): La Crosse encephalitis is a relatively uncommon arboviral disease that is found primarily east of the Mississippi River. About 90 cases are reported each year in the United States. The vector of LAC is a specific species of *Aedes* (*Aedes triseriatus*) called the tree-hole mosquito. The symptoms of LAC are similar to those of JE. Most severe cases of LAC, however, occur in children younger than 16.
- St. Louis encephalitis (SLE): SLE is considered a member of the JE virus family. It is transmitted by several species of *Culex* mosquitoes. SLE can be found throughout the United States but is most common in Florida and the Gulf Coast states. About 128 cases of SLE are reported in the United States each year. Most people with SLE have only mild symptoms, including fever and headache. Severe disease is characterized by headache, high fever, neck stiffness, stupor, disorientation, occasional convulsions, and

WWW.BOOKBAZ.IR

paralysis. The fatality rate ranges from 3% to 30% with the elderly most susceptible to a fatal outcome.

- Western equine encephalitis (WEE): The virus that causes Western equine encephalitis belongs to the same family of viruses as those that cause EEE and chikungunya. It is transmitted by mosquitoes of the genera *Culex* and *Culiseta*. WEE in the United States is found primarily west of the Mississippi but is relatively uncommon; only 700 cases in humans were confirmed between 1964 and 2014. The mortality rate of WEE is about 4%.
- West Nile virus (WNV): West Nile virus is another arbovirus in the JE family. First identified in Uganda in 1937, it has since spread around the world. The first cases in the United States were reported in 1999, with the first Canadian cases reported in 2001. The most common vectors of WNV are *Culex pipiens* and *Culex tarsalis*. About 80% of people infected with WNV have no symptoms. Another 19% have a flu-like illness characterized by fever, headaches, loss of appetite, muscle aches and pains, nausea and vomiting, and a skin rash. These symptoms may last for several weeks or even months; many of these patients take as long as 90 days to recover. About 1% of patients develop infections of the central nervous system: West Nile encephalitis, West Nile meningitis, or West Nile poliomyelitis, an inflammation of the spinal cord leading to paralysis. The Centers for Disease Control and Prevention (CDC) estimates that there have been over 1.5 million Americans infected with WNV since 1999, with 36,437 cases of severe WNV illness reported; of these, 15,774 resulted in WNV meningitis or encephalitis, and 1,538 cases were fatal. In 2013, 2,469 cases of WNV were reported in the United States, with 1,267 classified as severe disease.
- Dengue (pronounced DEN-gay): Dengue, also known as breakbone fever, is a mosquito-borne disease that was primarily confined to Asia and Africa prior to the twentieth century. It is now the most common arboviral disease in humans. It is carried by two species of *Aedes* mosquitoes, *Aedes aegypti* and *Aedes albopictus*. These mosquitoes frequently lay their eggs in water-filled containers close to human dwellings but are not easily controlled by standard spraying methods. Dengue was extremely rare in North America until the late 1990s but has since been reported in Texas, Hawaii, the Florida Keys, and Puerto Rico. The milder form of dengue is characterized by fever, headache, muscle pains, and a skin rash resembling measles. The disease can, however, progress to dengue hemorrhagic fever, a life-threatening illness that occurs in fewer than 5% of cases. Dengue hemorrhagic fever is characterized by the leakage of blood plasma from the capillaries into the abdominal and chest cavities, resulting in shock, internal bleeding and organ damage.
- Rift Valley fever (RVF): Rift Valley fever is primarily a disease of livestock that takes its name from the area of eastern Africa where it originated. It has since spread to Yemen, Saudi Arabia, and South Africa. Humans can get RVF from the bites of infected mosquitoes but are more likely to acquire the disease from exposure to the blood or body tissues of infected animals. The milder form of RVF in humans includes such symptoms as headache and fever lasting for about a week. The severe form includes encephalitis, blindness, and liver failure; about 1% of people who develop RVF die from the disease.
- Yellow fever: Yellow fever was at one time widespread in tropical and subtropical regions around the world but is now uncommon in the developed world because of a widely available vaccine. There are, however, about 200,000 cases of yellow fever and 30,000 deaths every year elsewhere in the world, with nearly 90% of these cases occurring in Africa. Transmitted by *Aedes aegypti* mosquitoes, yellow fever takes its name from the jaundice that results from liver damage caused by the virus in severe cases. Most cases of yellow fever are mild, with fever, headache, chills, back pain, loss of appetite, nausea, and vomiting that last about four to five days. About 15% of patients, however, develop a severe form of yellow fever characterized by jaundice, recurring fever, and bleeding from the eyes, mouth, and digestive tract. About 20% of severely ill patients die.
- Chikungunya: Chikungunya is an emerging viral disease transmitted by the yellow fever mosquito *Aedes aegypti* and the Asian tiger mosquito *Aedes albopictus*. Chikungunya outbreaks have occurred in countries in Africa, Asia, Europe, and the Indian and Pacific Oceans, but were not reported in the Americas until 2013, when an outbreak occurred in several countries in the Caribbean. In early 2014 the CDC recorded about 1,300 cases in U.S. citizens returning from travels to the Caribbean. Eleven local cases have since been reported in Florida. The symptoms of chikungunya fever include a sudden high fever (about 102°F); severe joint pain and joint swelling; back pain; and a rash that erupts about 3 days after the fever begins. Other symptoms may include headache, nausea, vomiting, and redness around the eyes. Fatal cases are rare, but patients may experience

chronic arthritis, joint pains, and emotional depression lasting for months.

Parasitic mosquito-borne diseases

Parasitic mosquito-borne diseases include:

- Malaria: Malaria is caused by a protozoan of the genus *Plasmodium*, with *P. falciparum* and *P. vivax* the species most likely to cause fatal illness in humans. The parasite is transmitted to humans by an infected female mosquito of the *Anopheles gambiae* species. Immature parasites injected in the mosquito's saliva first travel to the liver, where they reproduce asexually and produce numerous daughter cells called merozoites. The merozoites infect red blood cells, where they multiply until the cells burst. The new merozoites infect new red blood cells in turn, producing most of the classical symptoms of malaria. Symptoms include high fever, fatigue, headaches, and vomiting; in severe cases, the patient may develop jaundice, seizures, coma, and death. Complications of malaria include breathing problems, kidney failure, liver dysfunction, and miscarriage or stillbirth in pregnant women.
- Lymphatic filariasis: Filariasis is a disease of the lymphatic system caused by a parasitic roundworm, *Wuchereria bancrofti*, transmitted to humans by the bite of *Culex*, *Anopheles*, or *Aedes* mosquitoes. The infectious larval stage of *W. bancrofti* is deposited beneath the skin by the bite of an infected mosquito. The larvae mature into adult worms that live in the lymphatic system, where they infect lymph nodes, block the flow of lymph, and produce a condition called elephantiasis: massive swelling of the external genitals, the scrotum (in men), and the lower limbs. The mature worms also release immature larval forms known as microfilariae into the host's blood.
- Heartworm: Heartworm is a disease of domestic pets and some wildlife caused by a parasitic roundworm, *Dirofilaria immitis*. The disease affects the animal when a mosquito carrying the third-stage larvae of *D. immitis* bites it. The third-stage larvae molt into fourth-stage larvae, enter the major blood vessels, and lodge in the pulmonary artery and the right side of the heart, where they grow into adult worms, some as long as 10 to 12 inches in length. The worm burden in dogs causes coughing, exhaustion, and in extreme cases, congestive heart failure. Domestic cats are much less likely than dogs to develop heartworm infection, but are more difficult to treat. The first sign of the disease in cats may be wheezing or a heart murmur but is often sudden death.

Risk factors

Risk factors for mosquito-borne diseases include:

- Living in or traveling to tropical or subtropical regions of the world with poor sanitation and mosquito control
- Living in parts of the United States with warm humid climates
- Employment in an occupation that involves exposure to livestock or working in swamplands or marshy areas
- Age, with the very old and the very young most susceptible to mosquito-borne diseases
- Having an immune system weakened by taking immunosuppressive drugs or by such infections as HIV
- Having had an organ transplant
- Hypertension
- Diabetes mellitus
- Having personal characteristics that are attractive to mosquitoes: type O blood; a tendency to sweat heavily; pregnancy; a high level of body heat; and a high level of skin bacteria.

As far as is known, neither race nor sex are risk factors for mosquito-borne diseases

Demographics

The demographics of mosquito-borne diseases vary widely, from those that are endemic in large parts of the world and cause millions of cases of illness each year (207 million cases per year for malaria; as many as 500 million cases of dengue per year; and 120 million people in 73 countries with long-term **filariasis** infections) to those that cause only sporadic outbreaks affecting small numbers of people. While malaria was endemic in the southern United States until the 1940s, when insecticide application and control of water levels reduced the mosquito population, it is presently a rare disease, with about 1,500 cases reported annually—almost all of them in travelers returning from Africa and southern Asia.

Causes and symptoms

Mosquito-borne diseases are caused by viruses or parasites introduced into the human body through the bite of an infected mosquito. Mosquitoes lay their eggs in stagnant water and spend the first three of their four life stages (egg, larva, and pupa) in this aquatic environment. The adult bloodsucking insect emerges from the pupa and may have a lifespan ranging from a week to several months. To produce viable eggs, the female

WWW.BOOKBAZ.IR

mosquito must have a blood meal. The mosquito's saliva contains an anticoagulant to keep the host's blood from clotting while the mosquito draws up the blood; the saliva is also the main route for any disease agents carried by the mosquito to enter the host's body. If another mosquito bites the infected host, it can acquire the virus or parasite and transmit it in turn to another host. In addition to humans, birds, domestic pets, livestock, coyotes and other wild mammals, and pigs may be hosts for bloodsucking mosquitoes. Once the virus or parasite enters a human host, it will reproduce in the bloodstream (arboviral diseases and malaria) or the lymphatic system (filariasis).

Human-to-human transmission of arboviral diseases is very rare but can occur through **transfusion** of contaminated blood or transplanted organs. Cases of **dengue fever** traced to transfused blood were reported in Hong Kong and Singapore in 2008. A few cases have also been reported of maternal-fetal transmission of dengue. Last, in some parts of the world, human-to-human transmission of arboviruses has been traced to needles shared among intravenous drug abusers.

Diagnosis

The diagnosis of mosquito-borne disease begins with a careful patient history, including occupation and recent travel history to known areas where mosquito-borne diseases are endemic. The doctor should have a high index of suspicion for arboviral diseases and malaria in the United States, as these illnesses are relatively uncommon in most parts of the country and the initial symptoms (**headache**, **fever**, muscle pains, nausea) are nonspecific and may result from a number of other viral or bacterial infections. Laboratory confirmation of the diagnosis is therefore critical.

The most common laboratory tests for a mosquito-borne viral disease are a test of blood serum to detect antibodies to the virus or a test of cerebrospinal fluid to determine whether the infection has spread to the central nervous system. There are two types of antibodies that may be measured by enzyme-linked immunosorbent assay (ELISA): IgM and IgG. IgM antibodies are produced early in the course of an infection and are therefore tested in the blood of a symptomatic patient. IgG antibodies are produced later and may be tested to determine whether the patient was exposed to the arbovirus in the past. In some cases a panel of blood tests may be conducted to identify the specific arbovirus that is causing the infection. While antibody tests can indicate the presence of an arbovirus infection, they cannot be used to predict the severity of the patient's symptoms or indicate the prognosis.

A different type of test called the nucleic acid amplification test (NAAT) multiplies and measures the arbovirus's genetic material in order to confirm its presence in the patient's sample. This test is performed in only a few specialized laboratories but can be used to screen for the presence of an arbovirus in donated blood, tissues, or organs.

The doctor may order additional blood tests, including a **complete blood count**, coagulation studies, a metabolic panel, and measurement of liver enzymes to determine whether the patient's liver and other internal organs have been affected by severe disease. **Ultrasound** imaging may be done in cases of patients with dengue fever to detect the leakage of fluid into body cavities. CT and MRI imaging are not helpful in diagnosing St. Louis encephalitis, although they are useful in detecting changes in the brain in Japanese encephalitis, Eastern equine encephalitis, and Western equine encephalitis.

Filariasis amd malaria may be diagnosed by a smear of the patient's blood; the immature parasites are clearly visible. A blood test for the antigen to filariasis can also be used to confirm the diagnosis, while malaria can also be confirmed by a rapid diagnostic test (RDT) for antibodies to *P. falciparum*. A **chest x-ray** or ultrasound imaging may be used to detect the extent of blockage of the patient's lymphatic system in filariasis or respiratory symptoms in malaria.

Heartworm in domestic pets is almost always diagnosed as of 2014 by ELISA testing for the antigen to *D. immitis*. X rays may be used to determine the pet's prognosis.

Doctors in the United States are required by law to report the following mosquito-borne diseases (termed notifiable diseases) to the CDC: dengue, Eastern equine encephalitis, malaria, St. Louis encephalitis, West Nile fever, Western equine encephalitis, and yellow fever. The CDC maintains a national surveillance system for monitoring arboviral diseases called ArboNET.

Treatment

There are no specific antiviral medications to treat arboviral infections as of 2014. Patients are usually given supportive treatment, with bed rest, and **acetaminophen** to relieve fever, headache, and muscle aches. **Aspirin** and NSAIDs should be avoided. Patients with severe disease may require intravenous

fluids. Patients with Japanese encephalitis may require airway management or anticonvulsant medications to control seizures.

Lymphatic filariasis is treated with anthelminthic medications. Outside North America, albendazole is the drug most often used; in the United States and Canada, ivermectin, flubendazole, or diethylcarbamazine (DEC) are usually given. Patients in regions where the disease is endemic must be given annual doses of the medication for six to seven years in order to completely break the complex life cycle of *W. bancrofti*.

Treatment of malaria depends on several factors, including the severity of disease, the specific species of *Plasmodium* causing the infection, and the part of the world where the disease was contracted. These last two factors are critical because the malaria parasite has developed resistance to some medications in some areas. Drugs used to treat malaria include atovaquone-proguanil, chloroquine, mefloquine, quinine, and artemether-lumefantrine. Doxycycline or clindamycin may be used in combination with quinine. Artesunate, an intravenous medication, is not licensed for use in the United States.

Heartworm in domestic dogs can be treated with an arsenic-based drug called melarsomine dihydrochloride (Immiticide); in severe cases, the worms may be removed surgically. There are, unfortunately, no good treatments for cats, as an older medication called caparsolate can cause **pulmonary embolism** in a cat because the worms can break away as they die and block the pulmonary artery. If the cat is asymptomatic, it can clear the parasite on its own in two to three years, but should be monitored by a veterinarian every six months.

Prognosis

The prognosis of mosquito-borne diseases depends on the virulence of the specific disease agent and the patient's general health. Most mosquito-borne arboviral diseases cause either no symptoms or only mild flu-like symptoms in about 80% of infected humans. Mortality rates for severe disease range from 20% for yellow fever to about 1% for Rift Valley fever.

The prognosis of parasitic mosquito-borne diseases varies from 20% mortality for malaria to less than 1% for filariasis. While filariasis is rarely fatal, however, it is the second most widespread infectious cause (after **leprosy**) of lifelong disability in the world.

Prevention

As of 2014, preventive vaccines are available for Japanese encephalitis and yellow fever. There are vaccines for Eastern equine encephalitis and Western equine encephalitis for horses but none for humans. Vaccines for dengue, West Nile virus, Eastern equine encephalitis, and filariasis are in development.

Although there is no vaccine for malaria as of 2014, persons traveling to Africa, Asia, or parts of South America can lower their risk of contracting the disease by taking prophylactic doses of antimalarial medications like primaquine, chloroquine, mefloquine, or atovaquone-proguanil before travel. Details about specific drugs and dosages can be found at http://wwwnc.cdc.gov/travel/yellowbook/2014/chapter-3-infectious-diseases-related-to-travel/malaria#3938, Table 3–10.

KEY TERMS

Anthelminthic—Any medication that is used to rid the body of parasitic worms.

Emerging infectious disease (EID)—An infectious disease whose incidence has increased within the last 35 years and may increase further in the near future.

Encephalitis (plural, encephalitides)—Acute inflammation of the brain, which can be caused by viruses, bacteria, fungi, or parasites.

Endemic—Referring to a disease that is maintained in a population without the need for external inputs. The infection neither dies out nor increases exponentially.

Heartworm disease—A parasitic disease that affects dogs, cats, and ferrets, spread by mosquitoes from one infected pet to another. The larvae migrate to the arteries supplying the heart and lungs of infected animals, where they mature and reproduce.

Notifiable disease—Any disease that is required by law to be reported to public health authorities. In the United States, the CDC maintains a list of nationally notifiable diseases monitored by the National Notifiable Diseases Surveillance System (NNDSS).

Vector—In epidemiology, any person, animal, or microorganism that conveys an infectious disease organism to another living organism.

Zoonosis (plural, zoonoses)—Any disease that can be transmitted from other animals to humans, or from humans to other animals.

WWW.BOOKBAZ.IR

Heartworm in domestic pets can be prevented by medications that are 99% effective. Dogs can be given ivermectin, milbemycin, or moxidectin in pill form, moxidectin in injectable form, or selamectin in a topical formulation applied monthly. Cats can be protected with ivermectin, milbemycin, or selamectin, but must be given only formulations specifically approved for cats. A new topical preventive formulation containing eprinomectin appears to be equally effective for cats.

Other preventive measures recommended by the American Mosquito Control Association (AMCA) to lower the risk of mosquito bites include the "three Ds":

- Drain: Remove all standing water from areas near the house: clear roof gutters; change water in pet dishes and bird baths regularly; repair leaky outdoor faucets; turn over canoes and other boats; drill holes in the bottom of recycling bins; plug tree holes; and remove water from tarps or pool covers. It takes only a small amount of standing water to breed thousands of mosquitoes.
- Dress: Wear light-colored, loose-fitting clothing, as mosquitoes are attracted to dark colors. When practical, wear long-sleeved shirts and long pants.
- Defend: Use one of the four EPA-recommended mosquito repellents on exposed skin (not on clothing): DEET (N, N-diethyl toluamide); picaridin (KBR 3023); oil of lemon eucalyptus; or IR3535.

Motion sickness

Definition

Motion sickness is the uncomfortable **dizziness**, nausea, and **vomiting** that people experience when their sense of balance and equilibrium is disturbed by constant motion. Riding in a car, aboard a ship or boat, or riding on a swing all cause stimulation of the vestibular system and visual stimulation that often leads to discomfort. While motion sickness can be bothersome, it is not a serious illness, and can be prevented.

Demographics

Motion sickness is a common problem, with nearly 80% of the general population suffering from it at one time or another in their lives. People with migraine headaches or Ménière's syndrome, however, are more likely than others to have recurrent episodes of motion sickness. Researchers at the Naval Medical Center in San Diego, California, reported in 2003 that 70% of research subjects with severe motion sickness had abnormalities of the vestibular system; these abnormalities are often found in patients diagnosed with migraines or Ménière's disease.

While motion sickness may occur at any age, it is more common in children over the age of two, with the majority outgrowing this susceptibility.

Description

When looking at the causes of motion sickness, it is helpful to understand the role of the sensory organs. The sensory organs control a body's sense of balance by telling the brain what direction the body is pointing, the direction it is moving, and if it is standing still or turning. These messages are relayed by the inner ears (or labyrinth); the eyes; skin pressure receptors, such as in those in the feet; muscle and joint sensory receptors, which track what body parts are moving; and the central nervous system (the brain and spinal cord), which is responsible for processing all incoming sensory information.

Motion sickness and its symptoms arise when conflicting messages are sent to the central nervous system. An example of this phenomenon occurs while reading a book in the back seat of a moving car. The inner ears and skin receptors sense the motion, but the eyes register only the stationary pages of the book. This conflicting information may cause the usual motion sickness symptoms of dizziness, **nausea and vomiting**.

Causes and symptoms

While all five of the body's sensory organs contribute to motion sickness, excess stimulation to the vestibular system within the inner ear (the body's "balance center") has been shown to be one of the primary reasons for this condition. Balance problems, or vertigo, are caused by a conflict between what is seen and how the inner ear perceives it, leading to confusion in the brain. This confusion may result in higher heart rates, rapid breathing, nausea and sweating, along with dizziness and vomiting.

Pure optokinetic motion sickness is caused solely by visual stimuli, or what is seen. The optokinetic system is the reflex that allows the eyes to move when an object moves. Many people suffer when the object they view is rotating or swaying, even if they are standing still.

Additional factors that may contribute to the occurrence of motion sickness include:

- Poor ventilation.
- Anxiety or fear. Both have been found to lower a person's threshold for experiencing motion sickness symptoms.

WWW.BOOKBAZ.IR

- Food. It is recommended that a heavy meal of spicy and greasy foods be avoided before and during a trip.
- Alcohol. A drink is often thought to help calm the nerves, but in this case it could upset the stomach further. A hangover prior to the next morning's trip may also lead to motion sickness.
- Genetic factors. Research suggests that some people inherit a predisposition to motion sickness. This predisposition is more marked in some ethnic groups than in others. One study published in 2002 found that persons of Chinese or Japanese ancestry are significantly more vulnerable to motion sickness than persons of British ancestry.
- Pregnancy. Susceptibility in women to vomiting during pregnancy appears to be related to motion sickness, although the precise connections are not yet well understood.

Often viewed as a minor annoyance, some travelers are temporarily immobilized by motion sickness, and a few continue to feel its effects for hours and even days after a trip (the "mal d'embarquement" syndrome).

Diagnosis

Most cases of motion sickness are mild and self–treatable disorders. If symptoms such as dizziness become chronic, a doctor may be able to help alleviate the discomfort by looking further into a patient's general health. Questions regarding medications, head injuries, recent infections, and other questions about the ear and neurological system will be asked. An examination of the ears, nose, and throat, as well as tests of nerve and balance function, may also be completed.

Severe cases of motion sickness symptoms, and those that become progressively worse, may require additional, specific tests. Diagnosis in these situations deserves the attention and care of a doctor with specialized skills in diseases of the ear, nose, throat, equilibrium, and neurological system.

Treatment

There are a variety of medications to help ease the symptoms of motion sickness, and most of these are available without a prescription. Known as over-the-counter (OTC) medications, these products should be taken 30–60 minutes before traveling in order to prevent motion sickness symptoms, as well as during an extended trip.

Drugs

The following OTC drugs consist of ingredients that have been considered safe and effective for the treatment of motion sickness by the Food and Drug Administration (FDA):

- Marezine (and others). Includes the active ingredient cyclizine and is not for use in children under age six.
- Benadryl (and others). Includes the active ingredient diphenhydramine and is not for use in children under age six.
- Dramamine (and others). Includes the active ingredient dimenhydrinate and is not for use in children under age two.
- Bonine (and others). Includes the active ingredient meclizine and is not for use in children under age 12.

Each of the active ingredients listed above are **antihistamines** whose main side effect is drowsiness. Caution should be used when driving a vehicle or operating machinery, and alcohol should be avoided when taking any drug for motion sickness. Large doses of OTC drugs for motion sickness may also cause **dry mouth** and occasional blurred vision.

The side effects of antihistamine **antiemetics** indicate that they should not be used by members of flight crews responsible for the control of aircraft or for other tasks that require sustained attention and alertness.

KEY TERMS

Acupressure—A traditional Chinese medical technique based on the theory of *qi* (life energy) flowing in energy meridians or channels in the body. Applying pressure with the thumb and fingers to acupressure points is thought to relieve specific conditions and promote overall balance and health.

Acupuncture—Based on the same traditional Chinese medical foundation as acupressure, acupuncture uses sterile needles inserted at specific points to treat certain conditions or relieve pain.

Neurological system—The tissue that initiates and transmits nerve impulses, including the brain, spinal cord, and nerves.

Optokinetic—A reflex that causes a person's eyes to move when the person's field of vision moves.

Vertigo—The sensation of moving around in space, or objects moving around a person. It is a disturbance of equilibrium.

Vestibular system—The brain and parts of the inner ear that work together to detect movement and position.

PATRICIA SUZANNE COWINGS (1948–)

Patricia Suzanne Cowings was born on December 15, 1948, in New York City. She was one of four children born to Albert Cowings, a grocery store owner, and his wife Sadie. Cowings showed interest in science by the time she was eleven years old. She enrolled in the State University of New York at Stony Brook, earning her bachelor's degree with honors in 1970. She began her graduate work at the University of California at Davis where she was awarded both her master's and her doctoral degrees in 1973. Cowings received an associateship from the National Research Council that same year, which allowed her to complete two years of research at NASA's Ames Research Center. She has held a position as a researcher with Ames since 1977 and as of 2014 was the principal investigator of Psychophysiological Research Laboratories at NASA Ames Research Center (ARC), as well as a professor of psychiatry at the University of California, Los Angeles.

Cowings's work at Ames' Psychophysiological Research Laboratory led to major breakthroughs for astronauts. Her pioneering experiments with biofeedback as a method to control bodily functions has proven very effective for astronaut crews who experience "zero-gravity sickness syndrome." Her program was finally used during the 1992 *Endeavour* space flight. In 2014, Cowings was researching exercises that would allow astronauts to maintain muscle strength while in zero gravity. She has published numerous papers with her colleague and husband, William B. Toscano. In addition, she has written many articles, including "The Relationship of Motion Sickness Susceptibility to Learned Autonomic Control for Symptom Suppression" (1982), "Autogenic-Feedback Training as a Preventive Method for Space Adaptation Syndrome" (1985), and "Autogenic-Feedback Training: A Preventive Method for Motion and Space Sickness" (1990).

The FDA recommends that people with **emphysema**, chronic **bronchitis**, **glaucoma**, or difficulty urinating due to an **enlarged prostate** not use OTC drugs for motion sickness unless directed by their doctor.

Longer trips may require a prescription medication called scopolamine (Transderm Scop). Formerly used in the transdermal skin patch (now discontinued), travelers must now ask their doctor to prescribe it in the form of a gel. In gel form, scopolamine is most effective when smeared on the arm or neck and covered with a bandage.

Another prescription drug that is sometimes given for motion sickness is ondansetron (Zofran), which was originally developed to treat nausea associated with cancer **chemotherapy**. Unlike cyclizine, ondansetron appears to be safe for use in children under the age of six.

One newer class of anti–emetic drugs include compounds known as neurokinin–1 (substance P) antagonists. The neurokinins are usually prescribed for the control of nausea before surgery and following cancer chemotherapy, as well as preventing nausea in persons who have previously experienced severe motion sickness. The first of these new antiemetic drugs was known as aprepitant, and is sold under the trade name Emend.

Alternatives

Alternative treatments for motion sickness have become widely accepted as a standard means of care. Ginger (*Zingiber officinale*) in its various forms is often used to calm the stomach, and it is now known that the oils it contains (gingerols and shogaols) appear to relax the intestinal tract in addition to mildly depressing the central nervous system. Some of the most effective forms of ginger include the powdered, encapsulated form; ginger tea prepared from sliced ginger root; or candied pieces. All forms of ginger should be taken on an empty stomach.

Placing manual pressure on the Neiguan or Pericardium–6 **acupuncture** point (located about three finger–widths above the wrist on the inner arm), either by acupuncture, **acupressure**, or a mild, electrical pulse, has shown to be effective against the symptoms of motion sickness. Elastic wristbands sold at most drugstores are also used as a source of relief due to the pressure it places in this area. Pressing the small indentation (just below the earlobes in the indentations behind the jawbone) may also help in the functioning of the ear's balancing mechanism.

There are several homeopathic remedies that work specifically for motion sickness. They include *Cocculus*, *Petroleum*, and *Tabacum*. Alternative treatments should be used with care, as the benefits of many such treatments have not been confirmed by scientific research.

The National Aeronautics and Space Administration (NASA) has developed an additional treatment for motion sickness that has shown benefit for both military pilots and astronauts. NASA's autogenic feedback training exercises encourage pilots to reduce motion sickness symptoms by controlling their own responses to the sensations of flight using **biofeedback**

WWW.BOOKBAZ.IR

and self–suggestion exercises. After one six–hour training session, eighty percent of pilot volunteers who had previously experienced symptoms of motion sickness reported increased motion sickness tolerance. With more study, NASA anticipates that the program could provide similar benefit to persons experiencing motion sickness, extreme **fatigue**, jet–lag, **insomnia**, and high **stress** work environments.

Prognosis

While there is no cure for motion sickness, its symptoms can be controlled or even prevented. Most people respond successfully to the variety of treatments available, or avoid the unpleasant symptoms through prevention methods.

Prevention

Because motion sickness is easier to prevent than treat once it has begun, the best treatment is prevention. The following steps may help deter the unpleasant symptoms of motion sickness before they occur:

- Avoid reading while traveling, and do not sit in a backward facing seat.
- Always ride where the eyes may see the same motion that the body and inner ears feel. Safe positions include the front seat of the car while looking at distant scenery; the deck of a ship where the horizon can be seen; and sitting by the window of an airplane. The least motion on an airplane is in a seat over the wings.
- Maintain a fairly straight–ahead view.
- Eat a light meal before traveling, or if already nauseated, avoid food altogether.
- Avoid watching or talking to another traveler who is having motion sickness.
- Take motion sickness medicine at least 30–60 minutes before travel begins, or as recommended by a physician.
- Learn to live with the condition. Even those who frequently endure motion sickness can learn to travel by anticipating the conditions of their next trip. Research also suggests that increased exposure to the stimulation that causes motion sickness may help decrease its symptoms on future trips.

Movement disorders

Definition

Movement disorders are a group of diseases and syndromes affecting the ability to produce and control movement.

Description

Although it seems simple and effortless, normal movement in fact requires an astonishingly complex system of control. Disruption of any portion of this system can cause a person to produce movements that are too weak, too forceful, too uncoordinated, or too poorly controlled for the task at hand. Unwanted movements may occur at rest. Intentional movement may become impossible. Such conditions are called movement disorders.

Abnormal movements themselves are symptoms of underlying disorders. In some cases, the abnormal movements are the only symptoms. Disorders causing abnormal movements include:

- Parkinson's disease
- Parkinsonism caused by drugs or poisons
- Parkinson–plus syndromes (progressive supranuclear palsy, multiple system atrophy, and cortical–basal ganglionic degeneration)
- Huntington's disease
- Wilson's disease
- Inherited ataxias (Friedreich's ataxia, Machado–Joseph disease, and spinocerebellar ataxias)
- Tourette syndrome and other tic disorders
- Essential tremor
- Restless leg syndrome
- Dystonia
- Stroke
- Cerebral palsy
- Encephalopathies
- Intoxication
- Poisoning by carbon monoxide, cyanide, methanol, or manganese

Causes and symptoms

Causes

Movement is produced and coordinated by several interacting brain centers, including the motor cortex, the cerebellum, and a group of structures in the inner portions of the brain called the basal ganglia. Sensory information provides critical input on the current position and velocity of body parts, and spinal nerve cells (neurons) help prevent opposing muscle groups from contracting at the same time.

To understand how movement disorders occur, it is helpful to consider a normal voluntary movement, such as reaching to touch a nearby object with the right index finger. To accomplish the desired movement, the arm must be lifted and extended. The hand must be held out to align with the forearm, and the forefinger must be extended while the other fingers remain flexed.

THE MOTOR CORTEX. Voluntary motor commands begin in the motor cortex located on the outer, wrinkled surface of the brain. Movement of the right arm is begun by the left motor cortex, which generates a large volley of signals to the involved muscles. These electrical signals pass along upper motor neurons through the midbrain to the spinal cord. Within the spinal cord, they connect to lower motor neurons, which convey the signals out of the spinal cord to the surface of the muscles involved. Electrical stimulation of the muscles causes contraction, and the force of contraction pulling on the skeleton causes movement of the arm, hand, and fingers.

Damage to or death of any of the neurons along this path causes weakness or **paralysis** of the affected muscles.

ANTAGONISTIC MUSCLE PAIRS. This picture of movement is too simple, however. One important refinement to it comes from considering the role of opposing, or antagonistic, muscle pairs. Contraction of the biceps muscle, located on the top of the upper arm, pulls on the forearm to flex the elbow and bend the arm. Contraction of the triceps, located on the opposite side, extends the elbow and straightens the arm. Within the spine, these muscles are normally wired so that willed (voluntary) contraction of one is automatically accompanied by blocking of the other. In other words, the command to contract the biceps provokes another command within the spine to prevent contraction of the triceps. In this way, these antagonist muscles are kept from resisting one another. Spinal cord or brain injury can damage this control system and cause involuntary simultaneous contraction and spasticity, an increase in resistance to movement during motion.

THE CEREBELLUM. Once the movement of the arm is initiated, sensory information is needed to guide the finger to its precise destination. In addition to sight, the most important source of information comes from the position sense provided by the many sensory neurons located within the limbs (proprioception). Proprioception is the response allows a person to touch the nose with the finger even with the eyes closed. The balance organs in the ears provide important information about posture. Both postural and proprioceptive information are processed by a structure at the rear of the brain called the cerebellum. The cerebellum sends out electrical signals to modify movements as they progress, sculpting the barrage of voluntary commands into a tightly controlled, constantly evolving pattern. Cerebellar disorders cause inability to control the force, fine positioning, and speed of movements (ataxia). Disorders of the cerebellum may also impair the ability to judge distance so that a person under- or overreaches the target (dysmetria). Tremor during voluntary movements can also result from cerebellar damage.

THE BASAL GANGLIA. Both the cerebellum and the motor cortex send information to a set of structures

WWW.BOOKBAZ.IR

deep within the brain that help control involuntary components of movement (basal ganglia). The basal ganglia send output messages to the motor cortex, helping to initiate movements, regulate repetitive or patterned movements, and control muscle tone.

Circuits within the basal ganglia are complex. Within this structure, some groups of cells begin the action of other basal ganglia components and some groups of cells block the action. These complicated feedback circuits are not entirely understood. Disruptions of these circuits are known to cause several distinct movement disorders. A portion of the basal ganglia called the substantia nigra sends electrical signals that block output from another structure called the subthalamic nucleus. The subthalamic nucleus sends signals to the globus pallidus, which in turn blocks the thalamic nuclei. Finally, the thalamic nuclei send signals to the motor cortex. The substantia nigra, then, begins movement and the globus pallidus blocks it.

This complicated circuit can be disrupted at several points. For instance, loss of substantia nigra cells, as in Parkinson's disease, increases blocking of the thalamic nuclei, preventing them from sending signals to the motor cortex. The result is a loss of movement (motor activity), a characteristic of Parkinson's.

In contrast, cell loss in early Huntington's disease decreases blocking of signals from the thalamic nuclei, causing more cortex stimulation and stronger but uncontrolled movements.

Disruptions in other portions of the basal ganglia are thought to cause tics, **tremors**, dystonia, and a variety of other movement disorders, although the exact mechanisms are not well understood.

Some movement disorders, including Huntington's disease and inherited ataxias, are caused by inherited genetic defects. Some disease that cause sustained muscle contraction limited to a particular muscle group (focal dystonia) are inherited, but others are caused by **trauma**. The cause of most cases of Parkinson's disease is unknown, although genes have been found for some familial forms.

Symptoms

Abnormal movements are broadly classified as either hyperkinetic—too much movement—and hypokinetic—too little movement. Hyperkinetic movements include:

- Dystonia. Sustained muscle contractions, often causing twisting or repetitive movements and abnormal postures. Dystonia may be limited to one area (focal) or may affect the whole body (general). Focal dystonias may affect the neck (cervical dystonia or torticollis), the face (one–sided or hemifacial spasm, contraction of the eyelid or blepharospasm, contraction of the mouth and jaw or oromandibular dystonia, simultaneous spasm of the chin and eyelid or Meige syndrome), the vocal cords (laryngeal dystonia), or the arms and legs (writer's cramp, occupational cramps). Dystonia may be painful as well as incapacitating.
- Tremor. Uncontrollable (involuntary) shaking of a body part. Tremor may occur only when muscles are relaxed or it may occur only during an action or holding an active posture.
- Tics. Involuntary, rapid, nonrhythmic movement or sound. Tics can be controlled briefly.
- Myoclonus. A sudden, shock–like muscle contraction. Myoclonic jerks may occur singly or repetitively. Unlike tics, myoclonus cannot be controlled even briefly.
- Chorea. Rapid, nonrhythmic, usually jerky movements, most often in the arms and legs.
- Ballism. Like chorea, but the movements are much larger, more explosive and involve more of the arm or leg. This condition, also called ballismus, can occur on both sides of the body or on one side only (hemiballismus).
- Akathisia. Restlessness and a desire to move to relieve uncomfortable sensations. Sensations may include a feeling of crawling, itching, stretching, or creeping, usually in the legs.
- Athetosis. Slow, writhing, continuous, uncontrollable movement of the arms and legs.

Hypokinetic movements include:

- Bradykinesia. Slowness of movement.
- Freezing. Inability to begin a movement or involuntary stopping of a movement before it is completed.
- Rigidity. An increase in muscle tension when an arm or leg is moved by an outside force.
- Postural instability. Loss of ability to maintain upright posture caused by slow or absent righting reflexes.

Diagnosis

Diagnosis of movement disorders requires a careful medical history and a thorough physical and neurological examination. Brain imaging studies are usually performed. Imaging techniques include computed tomography scan (CT scan), **positron emission tomography** (PET), or **magnetic resonance imaging** (MRI) scans. Routine blood and urine analyses are performed. A **lumbar puncture** (spinal tap) may be

KEY TERMS

Botulinum toxin—Any of a group of potent bacterial toxins or poisons produced by different strains of the bacterium *Clostridium botulinum*. The toxins cause muscle paralysis, and thus force the relaxation of a muscle in spasm.

Cerebral palsy—A movement disorder caused by a permanent brain defect or injury present at birth or shortly after. It is frequently associated with premature birth. Cerebral palsy is not progressive.

Computed tomography (CT)—An imaging technique in which cross–sectional x rays of the body are compiled to create a three–dimensional image of the body's internal structures.

Encephalopathy—An abnormality in the structure or function of tissues of the brain.

Essential tremor—An uncontrollable (involuntary) shaking of the hands, head, and face. Also called familial tremor because it is sometimes inherited, it can begin in the teens or in middle age. The exact cause is not known.

Fetal tissue transplantation—A method of treating Parkinson's and other neurological diseases by grafting brain cells from human fetuses onto the basal ganglia. Human adults cannot grow new brain cells but developing fetuses can. Grafting fetal tissue stimulates the growth of new brain cells in affected adult brains.

Hereditary ataxia—One of a group of hereditary degenerative diseases of the spinal cord or cerebellum. These diseases cause tremor, spasm, and wasting of muscle.

Huntington's disease—A rare hereditary condition that causes progressive chorea (jerky muscle movements) and mental deterioration that ends in dementia. Huntington's symptoms usually appear in patients in their forties. There is no effective treatment.

Levodopa (L–dopa)—A substance used in the treatment of Parkinson's disease. Levodopa can cross the blood–brain barrier that protects the brain. Once in

necessary. Video recording of the abnormal movement is often used to analyze movement patterns and to track progress of the disorder and its treatment. **Genetic testing** is available for some forms of movement disorders.

Treatment

Treatment of a movement disorder begins with determining its cause. Physical and **occupational therapy** may help make up for lost control and strength. Drug therapy can help compensate for some imbalances of the basal ganglionic circuit. For instance, levodopa (L–dopa) or related compounds can substitute for lost dopamine–producing cells in Parkinson's disease. Conversely, blocking normal dopamine action is a possible treatment in some hyperkinetic disorders, including tics. Oral medications can also help reduce overall muscle tone. Local injections of botulinum toxin can selectively weaken overactive muscles in dystonia and spasticity. Destruction of peripheral nerves through injection of phenol can reduce spasticity. All of these treatments may have some side effects.

Surgical destruction or inactivation of basal ganglionic circuits has proven effective for Parkinson's disease and is being tested for other movement disorders. Transplantation of fetal cells into the basal ganglia has produced mixed results in Parkinson's disease.

Alternatives

There are several alternative therapies that can be useful when treating movement disorders. The progress made will depend on affected individuals and their condition. Among the therapies that may be helpful are **acupuncture**, homeopathy, touch therapies, postural alignment therapies, and **biofeedback**.

Prognosis

The prognosis for a patient with a movement disorder depends on the specific disorder.

Prevention

Prevention depends on the specific disorder.

the brain, it is converted to dopamine and thus can replace the dopamine lost in Parkinson's disease.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Parkinson's disease—A slowly progressive disease that destroys nerve cells in the basal ganglia and thus causes loss of dopamine, a chemical that aids in transmission of nerve signals (neurotransmitter). Parkinson's is characterized by shaking in resting muscles, a stooping posture, slurred speech, muscular stiffness, and weakness.

Positron emission tomography (PET)—A diagnostic technique in which computer–assisted x rays are used to track a radioactive substance inside a patient's body. PET can be used to study the biochemical activity of the brain.

Progressive supranuclear palsy—A rare disease that gradually destroys nerve cells in the parts of the brain that control eye movements, breathing, and muscle coordination. The loss of nerve cells causes palsy, or paralysis, that slowly gets worse as the disease progresses. The palsy affects ability to move the eyes, relax the muscles, and control balance.

Restless legs syndrome—A condition that causes an annoying feeling of tiredness, uneasiness, and itching deep within the muscle of the leg. It is accompanied by twitching and sometimes pain. The only relief is in walking or moving the legs.

Tourette syndrome—An abnormal condition that causes uncontrollable facial grimaces and tics and arm and shoulder movements. Tourette syndrome is perhaps best known for uncontrollable vocal tics that include grunts, shouts, and use of obscene language (coprolalia).

Wilson's disease—An inborn defect of copper metabolism in which free copper may be deposited in a variety of areas of the body. Deposits in the brain can cause tremor and other symptoms of Parkinson's disease.

Movement therapy

Definition

Movement therapy refers to a broad range of Eastern and Western movement approaches used to promote physical, mental, emotional, and spiritual well-being.

Purpose

The physical benefits of movement therapy include greater ease and range of movement, increased balance, strength and flexibility, improved muscle tone and coordination, joint resiliency, cardiovascular conditioning, enhanced athletic performance, stimulation of circulation, prevention of injuries, greater longevity, **pain** relief, and relief of rheumatic, neurological, spinal, **stress**, and respiratory disorders. Movement therapy can also be used as a **meditation** practice to quiet the mind, foster self-knowledge, and increase awareness. In addition, movement therapy is beneficial in alleviating emotional distress that is expressed through the body. These conditions include **eating disorders**, excessive clinging, and **anxiety** attacks. Since movements are related to thoughts and feelings, movement therapy can also bring about changes in

attitude and emotions. People report an increase in self-esteem and self-image. Communication skills can be enhanced and tolerance of others increased. The physical openness facilitated by movement therapy leads to greater emotional openness and creativity.

Description

Origins

Movement is fundamental to human life. In fact movement is life. Contemporary physics tells us that the universe and everything in it is in constant motion. We can move our body and at the most basic level our body is movement. According to the somatic educator Thomas Hanna, "The living body is a moving body—indeed, it is a constantly moving body." The poet and philosopher Alan Watts eloquently states a similar view, "A living body is not a fixed thing but a flowing event, like a flame or a whirlpool." Centuries earlier, the great Western philosopher Socrates understood what modern physics has proven, "The universe is motion and nothing else."

Since the beginning of time, indigenous societies around the world have used movement and dance for individual and community healing. Movement and song were used for personal healing, to create community, to ensure successful crops, and to promote fertility. Movement is still an essential part of many healing traditions and practices throughout the world.

Western movement therapies generally developed out of the realm of dance. Many of these movement approaches were created by former dancers or choreographers who were searching for a way to prevent injury, attempting to recover from an injury, or who were curious about the effects of new ways of moving. Some movement therapies arose out of the fields of **physical therapy**, psychology, and bodywork. Other movement therapies were developed as way to treat an incurable disease or condition.

Eastern movement therapies, such as **yoga**, **qigong**, and t'ai chi began as a spiritual or self-defense practices and evolved into healing therapies. In China, for example, Taoist monks learned to use specific breathing and movement patterns in order to promote mental clarity, physical strength, and support their practice of meditation. These practices, later known as qigong and t'ai chi eventually became recognized as ways to increase health and prolong life.

There are countless approaches to movement therapy. Some approaches emphasize awareness and attention to inner sensations. Other approaches use movement as a form of **psychotherapy**, expressing and working through deep emotional issues. Some approaches emphasize alignment with gravity and specific movement sequences, while other approaches encourage spontaneous movement. Some approaches are primarily concerned with increasing the ease and efficiency of bodily movement. Other approaches address the reality of the body "as movement" instead of the body as only something that runs or walks through space.

The term *movement therapy* is often associated with dance therapy. Some dance therapists work privately with people who are interested in personal growth. Others work in mental health settings with autistic, brain injured and learning disabled children, the elderly, and disabled adults.

Laban movement analysis (LMA), formerly known as Effort-Shape is a comprehensive system for discriminating, describing, analyzing, and categorizing movements. LMA can be applied to dance, athletic coaching, fitness, acting, psychotherapy, and a variety of other professions. Certified movement analysts can "observe recurring patterns, note movement preferences, asses physical blocks and dysfunctional movement patterns, and the suggest new movement patterns." As a student of Rudolf Laban, Irmgard Bartenieff developed his form of movement analysis into a system of body training or reeducation called Bartenieff fundamentals (BF). The basic premise of this work is that once the student experiences a physical foundation, emotional, and intellectual expression become richer. BF uses specific exercises that are practiced on the floor, sitting, or standing to engage the deeper muscles of the body and enable a greater range of movement.

Authentic movement (AM) is based upon Mary Starks Whitehouse's understanding of dance, movement, and depth psychology. There is no movement instruction in AM, simply a mover and a witness. The mover waits and listens for an impulse to move and then follows or "moves with" the spontaneous movements that arise. These movements may or may not be visible to the witness. The movements may be in response to an emotion, a dream, a thought, pain, joy, or whatever is being experienced in the moment. The witness serves as a compassionate, non judgmental mirror and brings a "special quality of attention or presence." At the end of the session the mover and witness speak about their experiences together. AM is a powerful approach for self development and awareness and provides access to preverbal memories, creative ideas, and unconscious movement patterns that limit growth.

WWW.BOOKBAZ.IR

Gabrielle Roth (5 Rhythms movement) and Anna Halprin have both developed dynamic movement practices that emphasize personal growth, awareness, expression, and community. Although fundamentally different forms, each of these movement/dance approaches recognize and encourage our inherent desire for movement.

Several forms of movement therapy grew out of specific bodywork modalities. **Rolfing** movement integration (RMI) and Rolfing rhythms are movement forms which reinforce and help to integrate the structural body changes brought about by the hands-on work of Rolfing (structural integration). RMI uses a combination of touch and verbal directions to help develop greater awareness of one's vertical alignment and habitual movement patterns. RMI teacher Mary Bond says, "The premise of Rolfing Movement Integration ... is that you can restore your structure to balance by changing the movement habits that perpetuate imbalance." Rolfing rhythms is a series of lively exercises designed to encourage awareness of the Rolfing principles of ease, length, balance, and harmony with gravity.

The movement education component of Aston-Patterning bodywork is called neurokinetics. This movement therapy teaches ways of moving with greater ease throughout every day activities. These movement patterns can also be used to release tension in the body. Aston fitness is an **exercise** program which includes warm-up techniques, exercises to increase muscle tone and stability, stretching, and cardiovascular fitness.

Rosen method movement (an adjunct to Rosen method bodywork) consists of simple fun movement exercises done to music in a group setting. Through gentle swinging, bouncing, and stretching every joint in the body experiences a full range of movement. The movements help to increase balance and rhythm and create more space for effortless breathing.

The movement form of **Trager psychophysical integration** bodywork, Mentastics, consists of fun, easy swinging, shaking, and stretching movements. These movements, developed by Dr. Milton Trager, create an experience of lightness and freedom in the body, allowing for greater ease in movement. Trager also worked successfully with **polio** patients.

Awareness through movement, the movement therapy form of the **Feldenkrais method**, consists of specific structured movement experiences taught as a group lesson. These lessons reeducate the brain without tiring the muscles. Most lessons are done lying down on the floor or sitting. Moshe Feldenkrais designed the lessons to "improve ability ... turn the impossible into the possible, the difficult into the easy, and the easy into the pleasant."

Ideokinesis is another movement approach emphasizing neuromuscular reeducation. Lulu Sweigart based her work on the pioneering approach of her teacher Mabel Elsworth Todd. Ideokinesis uses imagery to train the nervous system to stimulate the right muscles for the intended movement. If one continues to give the nervous system a clear mental picture of the movement intended, it will automatically select the best way to perform the movement. For example, to enhance balance in standing, Sweigart taught people to visualize "lines of movement" traveling through their bodies. Sweigart did not train teachers in ideokinesis but some individuals use ideokinetic imagery in the process of teaching movement.

The Mensendieck system of functional movement techniques is both corrective and preventative. Bess Mensendieck, a medical doctor, developed a series of exercises to reshape, rebuild, and revitalize the body. A student of this approach learns to use the conscious will to relax muscles and releases tension. There are more than 200 exercises that emphasize correct and graceful body movement through everyday activities. Unlike other movement therapy approaches this work is done undressed or in a bikini bottom, in front of mirrors. This allows the student to observe and feel where a movement originates. Success has been reported with many conditions including Parkinson's disease, muscle and joint injuries, and repetitive strain injuries.

The **Alexander technique** is another functional approach to movement therapy. In this approach a teacher gently uses hands and verbal directions to subtly guide the student through movements such as sitting, standing up, bending and walking. The Alexander technique emphasizes balance in the neck-head relationship. A teacher lightly steers the students head into the proper balance on the tip of the spine while the student is moving in ordinary ways. The student learns to respond to movement demands with the whole body, in a light integrated way. This approach to movement is particularly popular with actors and other performers.

Pilates or physical mind method is also popular with actors, dancers, athletes, and a broad range of other people. Pilates consists of over 500 exercises done on the floor or primarily with customized exercise equipment. The exercises combine sensory awareness and physical training. Students learn to move from a stable, central core. The exercises promote

strength, flexibility, and balance. Pilates training is increasingly available in sports medicine clinics, fitness centers, dance schools, spas, and physical therapy offices.

Many approaches to movement therapy emphasize awareness of internal sensations. Charlotte Selver, a student of somatic pioneer Elsa Gindler, calls her style of teaching sensory awareness (SA). This approach has influenced the thinking of many innovators, including Fritz Perls, who developed **gestalt therapy**. Rather than suggesting a series of structured movements, visualizations, or body positions, in SA the teacher outlines experiments in which one can become aware of the sensations involved in any movement. A teacher might ask the student to feel the movement of her breathing while running, sitting, picking up a book, etc. This close attunement to inner sensory experience encourages an experience of body-mind unity in which breathing becomes less restricted and posture, coordination, flexibility, and balance are improved. There may also be the experience of increased energy and aliveness.

Gerda Alexander Eutony (GAE) is another movement therapy approach that is based upon internal awareness. Through GAE one becomes a master of self-sensing and knowing which includes becoming sensitive to the external environment, as well. For example, while lying on the floor sensing the breath, skin or form of the body, one also senses the connection with the ground. GAE is taught in group classes or private lessons which also include hands-on therapy. In 1987, after two years of observation in clinics throughout the world, GAE became the first mind-body discipline accepted by the World Health Organization (WHO) as an alternative healthcare technique.

Kinetic awareness developed by dancer-choreographer Elaine Summers, emphasizes emotional and physical inquiry. Privately or in a group, a teacher sets up situations for the student to explore the possible causes of pain and movement restrictions within the body. Rubber balls of various sizes are used as props to focus attention inward, support the body in a stretched position and massage a specific area of the body. The work helps one to deal with chronic pain, move easily again after injuries and increase energy, flexibility, coordination, and comfort.

Body-mind centering (BMC) was developed by Bonnie Bainbridge Cohen and is a comprehensive educational and therapeutic approach to movement. BMC practitioners use movement, touch, **guided imagery**, developmental repatterning, dialogue, music, large balls, and other props in an individual session to meet the needs of each person. BMC encourages people to develop a sensate awareness and experience of the ligaments, nerves, muscles, skin, fluids, organs, glands, fat, and fascia that make up one's body. It has been effective in preventing and rehabilitating from chronic injuries and in improving neuromuscular response in children with **cerebral palsy** and other neurological disorders.

Continuum movement has also been shown to be effective in treating neurological disorders, including spinal chord injury. Developed by Emilie Conrad and Susan Harper, continuum movement is an inquiry into the creative flux of our body and all of life. Sound, breath, subtle and dynamic movements are explored that stimulate the brain and increase resonance with the fluid world of movement. The emphasis is upon unpredictable, spontaneous or spiral movements rather than a linear movement pattern. According to Conrad, "Awareness changes how we physically move. As we become more fluid and resilient so do the mental, emotional, and spiritual movements of our lives."

Eastern movement therapies such as yoga, t'ai chi, and qigong are also effective in healing and preventing a wide range of physical disorders, encouraging emotional stability, and enhancing spiritual awareness. There are a number of different approaches to yoga. Some emphasize the development of physical strength, flexibility, and alignment. Other forms of yoga emphasize inner awareness, opening, and meditation.

Precautions

People with acute injuries and chronic physical and mental conditions need to be careful when choosing a form of movement therapy. It is best to consult with a knowledgeable physician, physical therapist, or mental health therapist.

A special form of movement therapy known as constraint-induced movement therapy, or CIMT, is being used as of the early 2000s to rehabilitate the upper limbs of patients who have suffered a **stroke**, **traumatic brain injury**, or damage to the spinal cord. In CIMT, the arm that has been less affected by the injury is constrained by a sling for 90% of the patient's waking hours for a period of two weeks. The sling forces the patient to use the weaker arm more often; in addition, a physical therapist works with the patient to practice repetitive motions with the weaker arm. CIMT also appears to be useful in treating children

WWW.BOOKBAZ.IR

with muscular weakness on one side of the body caused by cerebral palsy.

Research and general acceptance

Although research has documented the beneficial effects of dance therapy, qigong, t'ai chi, yoga, Alexander technique, awareness through movement (Feldenkrais), and Rolfing, other forms of movement therapy have not been as thoroughly researched.

CIMT has become widely accepted in **rehabilitation** medicine since its introduction in the mid-1990s, although some doctors still consider it experimental. Further research in CIMT is being carried out by the National Institute of Neurological Disorders and Stroke (NINDS), one of the National Institutes of Health.

MRSA infections

Definition

MRSA infections are caused by methicillin-resistant *Staphylococcus aureus*, strains of staphylococcus bacteria (often called staph) that do not respond to some classes of **antibiotics**. There are two types of MRSA infections: healthcare-associated MRSA (HA-MRSA) is contracted in hospitals and other healthcare facilities such as nursing homes and dialysis centers; community-associated MRSA (CA-MRSA) are infections in people who have not been hospitalized or undergone a medical procedure during the previous year.

Demographics

MRSA was first isolated in the United States in 1968. By the early 1990s, it accounted for 20–25% of staph infections in hospitalized patients. In 2005, there were 111,261 life-threatening MRSA infections and approximately 18,650 deaths in the United States, about 85% of which were HA-MRSA. Infection rates were highest among people aged 65 or older, and African Americans were affected at twice the rate of whites, possibly due to higher rates of chronic illness. In sharp contrast, in 2011, there were 80,461 MRSA cases nationwide, a 31% decrease, and the majority were CA-MRSA. Although adult cases were decreasing, MRSA incidence in children was increasing. By 2013, MRSA was disproportionately affecting African American infants and children.

MRSA infections among National Football League (NFL) players have garnered media attention. Between 2003 and 2005, there were 60 MRSA infections among NFL players. This number dropped to 33 between 2006 and 2008.

Description

MRSA belongs to an emerging category of antibiotic-resistant bacteria that constitute a serious worldwide **public health** threat. Methicillin is an antibiotic that has been used successfully to treat infections caused by *S. aureus*. These staph bacteria are found on the skin and in the noses of approximately 33% of the general population and are usually harmless. If they enter the body through a cut or other wound, they typically cause only minor skin infections in healthy people or infections that are readily treated with antibiotics. Over the years, however, staph bacteria have mutated into MRSA strains that are resistant to beta-lactam antibiotics, including methicillin,

oxacillin, penicillin, and amoxicillin. When MRSA invades the skin and tissues beneath the skin, it can cause abscesses and ulcerations that may spread through the bloodstream and become life-threatening infections affecting the lungs, heart, joints, and bones. As of 2013, the U.S. Centers for Disease Control and Prevention (CDC) estimated that less than 2% of the general population carried MRSA; however, its threat level was set at "serious."

Traditional HA-MRSA strains are particularly deadly because they infect people in hospitals and other healthcare settings who are already in a weakened state from other medical conditions. However, the CA-MRSA strains that emerged since the end of the twentieth century are transmitted between healthy people outside healthcare settings.

The rise of MRSA and other antibiotic-resistant bacteria has been linked to years of antibiotic overuse. Because antibiotics do not kill all of the bacteria that are present, they promote the emergence of resistance: Some bacteria mutate to survive treatment with an antibiotic and pass on their resistance genes to other bacteria. Resistance to one antibiotic often confers resistance to a whole class of antibiotics. It is estimated that about half of human antibiotic use is inappropriate, since antibiotics are commonly prescribed for colds, flu, and other viral infections that do not respond to them, as well as for simple bacterial infections that normally clear on their own. Furthermore, in the United States, antibiotics are routinely administered to diary cows, beef cattle, pigs, and chickens to prevent the spread of infections among tightly packed livestock in industrial facilities, as well as to make the animals grow faster. More than 70% of antibiotic use in the United States is in animals. Thus, antibiotics—and antibiotic-resistant bacteria—can enter the human food chain. Antibiotics can also find their way into drinking water when runoff from animal feedlots contaminates streams and groundwater.

MRSA have been found in low numbers in retail meat products, as well as in dogs, cats, pigs, sheep, poultry, horses, cattle, rabbits, and various exotic animals. It is a growing problem in veterinary hospitals and intensive livestock facilities. Scientists believe that these MRSA strains originated in humans. Although strains infecting dogs and cats have not yet become host-adapted, strains infecting horses and livestock are readily transmitted between animals.

Risk factors

Risk factors for HA-MRSA include:

- hospitalization, especially in the elderly and those with weakened immune systems
- the use of invasive medical devices—such as intravenous lines, urinary catheters, or artificial joints—that provide MRSA entry into the body
- surgery
- treatment in a kidney dialysis center
- residing in a long-term care facility such as a nursing home

Most people are regularly exposed to CA-MRSA, but the intact skin protects against infection. However, MRSA readily spreads by skin-to-skin contact and can enter the body through cuts or abrasions. Risk factors for CA-MRSA include:

- contact sports, such as football and wrestling
- use of weight rooms
- sharing items such as towels or razors
- living or working in crowded or unsanitary conditions, including childcare centers, military camps, or jails, all of which have experienced MRSA outbreaks
- men having sex with men
- injecting illegal drugs
- obtaining tattoos

Causes and symptoms

The skin of healthy people is often colonized with staph that does not usually cause infection or symptoms. However, MRSA colonization can be readily transmitted to others. HA-MRSA is spread primarily through the hands of healthcare workers and patients sharing facilities. Hands become contaminated with MRSA by contact with infected patients or contaminated surfaces. CA-MRSA is spread by skin-to-skin contact or contact with contaminated objects.

Symptoms of MRSA infections vary. Skin infections usually cause small red pimples or **boils** that may be swollen, painful, and drain pus. CA-MRSA infections frequently begin as a painful boil. If the skin is rubbed or cut, MRSA can enter the body, especially in areas with more body hair, and quickly turn into deep, painful abscesses. MRSA infections in surgical **wounds**, the bloodstream, bones, joints, heart valves, or lungs are potentially life-threatening. Symptoms of serious MRSA infection may include:

- rash
- wounds that do not heal
- cough or shortness of breath

WWW.BOOKBAZ.IR

- fatigue
- fever and chills
- chest pain
- muscle aches
- headache

Diagnosis

Examination

Prompt diagnosis and treatment of MRSA are crucial. A physical exam and medical history will be performed.

Tests

MRSA is diagnosed by testing a tissue sample or nasal secretions for signs of staph bacteria. The sample is sent to a lab where it is incubated in a dish of nutrients that promotes the growth of staph colonies, which can then be identified. The test results will indicate which antibiotic can be used to treat the infection. Because it takes about 48 hours to grow the bacteria, blood tests that distinguish between MRSA DNA and DNA from methicillin-sensitive staph within two hours are often used.

Procedures

Various procedures are used to diagnose widespread or systemic MRSA infections.

Treatment

The first-line treatment for mild-to-moderate MRSA skin infections is surgical incision and drainage of the infection rather than antibiotics. However, severe MRSA infections are becoming more difficult to treat.

Drugs

Both HA-MRSA and CA-MRSA continue to respond to certain antibiotics, but the options are often extremely limited. Hospitals and other healthcare facilities generally rely on the antibiotic vancomycin. For serious infections, vancomycin may be administered intravenously, often for several weeks. However, some HA-MRSA strains are vancomycin-resistant, and as of 2013 there was growing concern because *S. aureus* appeared to be developing resistance faster than new antibiotics were being developed.

Alternatives

There are no alternatives to surgical draining of an **abscess** or antibiotics for treating MRSA infections.

Home remedies

Sores or wounds should be kept covered with a clean bandage. People should never attempt to open or drain infections themselves.

Prognosis

The prognosis for MRSA infections varies with the type and severity of the infection and the patient's overall health. Appropriately treated, mild CA-MRSA almost always results in full recovery. People who are already ill or have weakened immune systems or MRSA-related lung infections are difficult to treat. MRSA-related **pneumonia** and blood infections have high mortality rates.

Mucopolysaccharidoses

Definition

Mucopolysaccharidosis (MPS) is a general term for a number of inherited diseases that are caused by the accumulation of mucopolysaccharides, resulting in problems with an individual's development. With each condition, mucopolysaccharides accumulate in the cells and tissues of the body because of a deficiency of a specific enzyme. The specific enzyme that is deficient or absent is what distinguishes one type of MPS from another. However, before these enzymes were identified, the MPS disorders were diagnosed by the signs and symptoms that an individual expressed. The discovery of these enzymes resulted in a reclassification of some of the MPS disorders. These conditions are often referred to as MPS I, MPS II, MPS III, MPS IV, MPS VI, MPS VII, and MPS IX. However, these conditions are also referred to by their original names, which are Hurler, Hurler-Scheie, Scheie (all MPS I), Hunter (MPS II), Sanfilippo (MPS III), Morquio (MPS IV), Maroteaux-Lamy (MPS VI), Sly (MPS VII), and Hyaluronidase deficiency (MPS IX).

Description

Mucopolysaccharides are long chains of sugar molecules that are essential for building the bones, cartilage, skin, tendons, and other tissues in the body. Normally, the human body continuously breaks down and builds mucopolysaccharides. Another name for mucopolysaccharides is glycosaminoglycans (GAGs). There are many different types of GAGs and specific GAGs are unable to be broken down in each of the MPS conditions. There are several enzymes involved in breaking down each GAG and a deficiency or absence of any of the essential enzymes can cause the GAG to not be broken down completely and result in its accumulation in the tissues and organs in the body. In some MPS conditions, in addition to the GAG being stored in the body, some of the incompletely broken down GAGs can leave the body via the urine. When too much GAG is stored, organs and tissues can be damaged or not function properly.

Genetic profile

Except for MPS II, the MPS conditions are inherited in an autosomal recessive manner. MPS conditions occur when both of an individual's genes that produce the specific enzyme contain a mutation, causing them to not work properly. When both genes do not work properly, either none or a reduced amount of the enzyme is produced. An individual with an autosomal recessive condition inherits one of those non-working genes from each parent. These parents are called "carriers" of the condition. When two people are known carriers for an autosomal recessive condition, they have a 25% chance with each **pregnancy** to have a child affected with the disease. Some individuals with MPS do have children of their own. Children of parents who have an autosomal recessive condition are all carriers of that condition. These children are not at risk to develop the condition unless the other parent is a carrier or affected with the same autosomal recessive condition.

Unlike the other MPS conditions, MPS II is inherited in an X-linked recessive manner. This means that the gene causing the condition is located on the X chromosome, one of the two sex chromosomes. Since a male has only one X chromosome, he will have the disease if the X chromosome inherited from his mother carries the defective gene. Females, because they have two X chromosomes, are called "carriers" of the condition if only one of their X chromosomes has the gene that causes the condition, while the other X chromosome does not.

WWW.BOOKBAZ.IR

Causes and symptoms

Each type of MPS is caused by a deficiency of one of the enzymes involved in breaking down GAGs. It is the accumulation of the GAGs in the tissues and organs in the body that cause the wide array of symptoms characteristic of the MPS conditions. The accumulating material is stored in cellular structures called lysosomes, and these disorders are also known as lysosomal storage diseases.

MPS I

MPS I is caused by a deficiency of the enzyme alpha-L-iduronidase. Three conditions, Hurler, Hurler-Scheie, and Scheie syndromes, all are caused by a deficiency of this enzyme. Initially, these three conditions were felt to be separate because each were associated with different physical symptoms and prognoses. However, once the underlying cause of these conditions was identified, it was realized that these three conditions were all variants of the same disorder. The gene involved with MPS I is located on chromosome 4p16.3.

MPS I H (HURLER SYNDROME). It has been estimated that approximately one baby in 100,000 will be born with Hurler syndrome. Individuals with Hurler syndrome tend to have the most severe form of MPS I. Symptoms of Hurler syndrome are often evident within the first year or two after birth. Often these infants begin to develop as expected, but then reach a point where they begin to lose the skills that they have learned. Many of these infants may initially grow faster than expected, but their growth slows and typically stops by age three. Facial features also begin to appear "coarse." They develop a short nose, flatter face, thicker skin, and a protruding tongue. Additionally, their heads become larger and they develop more hair on their bodies with the hair becoming coarser. Their bones are also affected, with these children usually developing joint **contractures** (stiff joints), **kyphosis** (a specific type of curve to the spine), and broad hands with short fingers. Many of these children experience breathing difficulties, and respiratory infections are common. Other common problems include heart valve dysfunction, thickening of the heart muscle (**cardiomyopathy**), enlarged spleen and liver, clouding of the cornea, **hearing loss**, and **carpal tunnel syndrome**. These children typically do not live past age 12.

MPS I H/S (HURLER-SCHEIE SYNDROME). Hurler-Scheie syndrome is felt to be the intermediate form of MPS I, meaning that the symptoms are not as severe as those in individuals who have MPS I H but not as mild as those in MPS I S. Approximately one baby in 115,000 will be born with Hurler-Scheie syndrome. These individuals tend to be shorter than expected, and they can have normal intelligence, however, some individuals with MPS I H/S will experience learning difficulties. These individuals may develop some of the same physical features as those with Hurler syndrome, but usually they are not as severe. The prognosis for children with MPS I H/S is variable with some individuals dying during childhood, while others living to adulthood.

MPS I S (SCHEIE SYNDROME). Scheie syndrome is considered the mild form of MPS I. It is estimated that approximately one baby in 500,000 will be born with Scheie syndrome. Individuals with MPS I S usually have normal intelligence, but there have been some reports of individuals with MPS I S developing psychiatric problems. Common physical problems include corneal clouding, heart abnormalities, and orthopedic difficulties involving their hands and back. Individuals with MPS I S do not develop the facial features seen with MPS I H and usually these individuals have a normal life span.

MPS II (Hunter syndrome)

Hunter syndrome is caused by a deficiency of the enzyme iduronate-2-sulphatase. All individuals with Hunter syndrome are male, because the gene that causes the condition is located on the X chromosome, specifically Xq28. Like many MPS conditions, Hunter syndrome is divided into two groups, mild and severe. It has been estimated that approximately 1 in 110,000 males are born with Hunter syndrome, with the severe form being three times more common than the mild form. The severe form is felt to be associated with progressive intellectual and physical disability, with most individuals dying before age 15. In the milder form, most of these individuals live to adulthood and have normal intelligence or only mild mental impairments. Males with the mild form of Hunter syndrome develop physical differences similar to the males with the severe form, but not as quickly. Men with mild Hunter syndrome can have a normal life span and some have had children. Most males with Hunter syndrome develop joint stiffness, chronic **diarrhea**, enlarged liver and spleen, heart valve problems, hearing loss, kyphosis, and tend to be shorter than expected. These symptoms tend to progress at a different rate depending on if an individual has the mild or severe form of MPS II.

MPS III (Sanfilippo syndrome)

MPS III, like the other MPS conditions, was initially diagnosed by the individual having certain

physical characteristics. It was later discovered that the physical symptoms associated with Sanfilippo syndrome could be caused by a deficiency in one of four enzymes. Each type of MPS III is now subdivided into four groups, labeled A-D, based on the specific enzyme that is deficient. All four of these enzymes are involved in breaking down the same GAG, heparan sulfate. Heparan sulfate is mainly found in the central nervous system and accumulates in the brain when it cannot be broken down because one of those four enzymes are deficient or missing.

MPS III is a variable condition with symptoms beginning to appear between ages two and six years of age. Because of the accumulation of heparan sulfate in the central nervous system, the central nervous system is severely affected. In MPS III, signs that the central nervous system is degenerating usually are evident in most individuals between ages six and 10. Many children with MPS III will develop seizures, sleeplessness, thicker skin, joint contractures, enlarged tongues, cardiomyopathy, behavior problems, and intellectual disabilities (ID). The life expectancy in MPS III is also variable. On average, individuals with MPS III live until they are teenagers, with some living longer and others not that long.

MPS IIIA (SANFILIPPO SYNDROME TYPE A). MPS IIIA is caused by a deficiency of the enzyme heparan N-sulfatase. Type IIIA is felt to be the most severe of the four types, in which symptoms appear and death occurs at an earlier age. A study in British Columbia estimated that one in 324,617 live births are born with MPS IIIA. MPS IIIA is the most common of the four types in Northwestern Europe. The gene that causes MPS IIIA is located on the long arm of chromosome 17 (location 17q25).

MPS IIIB (SANFILIPPO SYNDROME TYPE B). MPS IIIB is due to a deficiency in N-acetyl-alpha-D-glucosaminidase (NAG). This type of MPS III is not felt to be as severe as Type IIIA and the characteristics vary. Type IIIB is the most common of the four in southeastern Europe. The gene associated with MPS IIIB is also located on the long arm of chromosome 17 (location 17q21).

MPS IIIC (SANFILIPPO SYNDROME TYPE C). A deficiency in the enzyme acetyl-CoA-alpha-glucosaminide acetyltransferase causes MPS IIIC. This is considered a rare form of MPS III. The gene involved in MPS IIIC is believed to be located on chromosome 14.

MPS IIID (SANFILIPPO SYNDROME TYPE D). MPS IIID is caused by a deficiency in the enzyme N-acetylglucosamine-6-sulfatase. This form of MPS III is also rare. The gene involved in MPS IIID is located on the long arm of chromosome 12 (location 12q14).

MPS IV (Morquio syndrome)

As with several of the MPS disorders, Morquio syndrome was diagnosed by the presence of particular signs and symptoms. However, it is now known that the deficiency of two different enzymes can cause the characteristics of MPS IV. These two types of MPS IV are called MPS IV A and MPS IV B. MPS IV is also variable in its severity. The intelligence of individuals with MPS IV is often completely normal. In individuals with a severe form, skeletal abnormalities can be extreme and include dwarfism, kyphosis (backward-curved spine), prominent breastbone, flat feet, and knock-knees. One of the earliest symptoms seen in this condition usually is a difference in the way the child walks. In individuals with a mild form of MPS IV, limb stiffness, and joint **pain** are the primary symptoms. MPS IV is one of the rarest MPS disorders, with approximately one baby in 300,000 born with this condition.

MPS IV A (MORQUIO SYNDROME TYPE A). MPS IV A is the "classic" or the severe form of the condition and is caused by a deficiency in the enzyme galactosamine-6-sulphatase. The gene involved with MPS IV A is located on the long arm of chromosome 16 (location 16q24.3).

MPS IV B (MORQUIO SYNDROME TYPE B). MPS IV B is considered the milder form of the condition. The enzyme, beta-galactosidase, is deficient in MPS IV B. The location of the gene that produces beta-galactosidase is located on the short arm of chromosome 3 (location 3p21).

MPS VI (Maroteaux-Lamy syndrome)

MPS VI, which is another rare form of MPS, is caused by a deficiency of the enzyme N-acetylglucosamine-4-sulphatase. This condition is also variable; individuals may have a mild or severe form of the condition. Typically, the nervous system or intelligence of an individual with MPS VI is not affected. Individuals with a more severe form of MPS VI can have airway obstruction, develop **hydrocephalus** (extra fluid accumulating in the brain) and have bone changes. Additionally, individuals with a severe form of MPS VI are more likely to die while in their teens. With a milder form of the condition, individuals tend to be shorter than expected for their age, develop corneal clouding, and live longer. The gene involved

WWW.BOOKBAZ.IR

in MPS VI is believed to be located on the long arm of chromosome 5 (approximate location 5q11-13).

MPS VII (Sly syndrome)

MPS VII is an extremely rare form of MPS and is caused by a deficiency of the enzyme beta-glucuronidase. It is also highly variable, but symptoms are generally similar to those seen in individuals with Hurler syndrome. The gene that causes MPS VII is located on the long arm of chromosome 7 (location 7q21).

MPS IX (Hyaluronidase deficiency)

MPS IX is a condition that was first described in 1996 and has been grouped with the other MPS conditions by some researchers. MPS IX is caused by the deficiency of the enzyme hyaluronidase. In the few individuals described with this condition, the symptoms are variable, but some develop soft-tissue masses (growths under the skin). Also, these individuals are shorter than expected for their age. The gene involved in MPS IX is believed to be located on the short arm of chromosome 3 (possibly 3p21.3-21.2)

Many individuals with an MPS condition have problems with airway constriction. This constriction may be so serious as to create significant difficulties in administering general **anesthesia**. Therefore, it is recommended that surgical procedures be performed under local anesthesia whenever possible.

Diagnosis

While a diagnosis for each type of MPS can be made on the basis of the physical signs described above, several of the conditions have similar features. Therefore, enzyme analysis is used to determine the specific MPS disorder. Enzyme analysis usually cannot accurately determine if an individual is a carrier for a MPS condition. This is because the enzyme levels in individuals who are not carriers overlaps the enzyme levels seen in those individuals who are carrier for a MPS. With many of the MPS conditions, several mutations have been found in each gene involved that can cause symptoms of each condition. If the specific mutation is known in a family, DNA analysis may be possible.

Once a couple has had a child with an MPS condition, prenatal diagnosis is available to them to help determine if a fetus is affected with the same MPS as their other child. This can be accomplished through testing samples using procedures such as an **amniocentesis** or **chorionic villus sampling** (CVS). Each of these procedures has its own risks, benefits, and limitations.

KEY TERMS

Cardiomyopathy—A thickening of the heart muscle.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Joint contractures—Stiffness of the joints that prevents full extension.

Kyphosis—An abnormal outward curvature of the spine, with a hump at the upper back.

Lysosome—Membrane-enclosed compartment in cells, containing many hydrolytic enzymes; where large molecules and cellular components are broken down.

Mucopolysaccharide—A complex molecule made of smaller sugar molecules strung together to form a chain. Found in mucous secretions and intercellular spaces.

Recessive gene—A type of gene that is not expressed as a trait unless inherited by both parents.

X-linked gene—A gene carried on the X chromosome, one of the two sex chromosomes.

Treatment

There is no cure for mucopolysaccharidosis. There are several types of experimental therapies that are being investigated. Typically, treatment involves trying to relieve some of the symptoms. For MPS I and VI, **bone marrow transplantation** has been attempted as a treatment option. In those conditions, bone marrow transplantation has sometimes been found to help slow down the progression or reverse some of symptoms of the disorder in some children. The benefits of a bone marrow transplantation are more likely to be noticed when performed on children under two years of age. However it is not certain that a bone marrow transplant can prevent further damage to certain organs and tissues, including the brain. Furthermore, bone marrow transplantation is not felt to be helpful in some MPS disorders and there are risks, benefits, and limitations with this procedure. In 2000, ten individuals with MPS I received recombinant human alpha-L-iduronidase every week for one year. Those individuals showed an improvement with some of their symptoms. Additionally, there is ongoing research involving gene replacement therapy (the insertion of normal copies of a gene into the cells of patients whose gene copies are defective).

Prevention

No specific preventive measures are available for genetic diseases of this type. For some of the MPS diseases, biochemical tests are available that will identify healthy individuals who are carriers of the defective gene, allowing them to make informed reproductive decisions. There is also the availability of prenatal diagnosis for all MPS disease to detect affected fetuses.

Mucormycosis

Definition

Mucormycosis is a rare but often fatal disease caused by certain fungi. It is sometimes called zygomycosis or phycomycosis. Mucormycosis is an opportunistic infection that typically develops in patients with weakened immune systems, diabetes, kidney failure, organ transplants, or **chemotherapy** for cancer. It may also develop in patients receiving an iron chelating drug called desferrioxamine (Desferal) as treatment for acute iron **poisoning**.

Description

In the United States, mucormycosis is most likely to develop in the patient's nasal area or in the lungs; however, it may also develop on the skin or in the digestive tract. Gastrointestinal disease usually develops only in severely malnourished patients. Cutaneous mucormycosis is most likely to develop under occlusive surgical dressings. Occlusive dressings are intended to keep air out of incisions or other **wounds**, but they also trap body heat and moisture.

The incidence of the disease is difficult to evaluate because it is very rare; however, the rate seems to be increasing. One American cancer center reported in 2000 that mucormycosis was found in 0.7% of patients at **autopsy** and in 20 patients per 100,000 admissions to the center. The most recent mortality statistics from the Centers for Disease Control and Prevention (CDC) indicate that a total of 22 Americans died from mucormycosis in 2001—1 from pulmonary mucormycosis, 5 from rhinocerebral mucormycosis, 2 from disseminated mucormycosis, and 14 from unspecified forms of the disease.

As far as is known, mucormycosis affects members of either sex and all races equally, although the pulmonary form of the disease is somewhat more common in men than in women. Mucormycosis may develop in patients in any age group, including newborns.

Rhinocerebral mucormycosis

Rhinocerebral mucormycosis is an infection of the nose, eyes, and brain. The fungus destroys the tissue of the nasal passages, sinuses, or hard palate, producing a black or pus-filled discharge and visible patches of dying tissue. The patient will typically

WWW.BOOKBAZ.IR

have **fever**, **pain**, and forward bulging of the eyes (proptosis). The fungus then invades the tissues around the eye socket and eventually the brain. At that point the patient may have convulsions or **paralysis** on one side of the body.

Pulmonary mucormycosis

Most patients with the pulmonary form of the disease are being treated for leukemia. The fungus enters the patient's lungs, where it eventually invades a major blood vessel, causing the patient to **cough** up blood or hemorrhage into the lungs.

Gastrointestinal mucormycosis

Gastrointestinal mucormycosis has been reported in premature or low-birth-weight infants as well as malnourished adults. It may lead to intestinal perforation and other complications requiring immediate surgery. A Spanish hospital reported in 2004 on an outbreak of gastrointestinal mucormycosis that affected five patients in an ICU over a 14-week period. Two of the patients died. The outbreak was eventually traced to a supply of wooden tongue depressors that had been contaminated by two species of *Rhizopus* fungi.

Causes and symptoms

Mucormycosis is caused by fungi of several different species, including *Mucor*, *Rhizopus*, *Absidia*, and *Rhizomucor*. When these organisms gain access to the mucous membranes of the patient's nose or lungs, they multiply rapidly and invade the nearby blood vessels. The fungi destroy soft tissue and bone, as well as the walls of blood vessels.

The early symptoms of rhinocerebral mucormycosis include fever, sinus pain, **headache**, and **cellulitis**. As the fungus reaches the eye tissues, the patient develops dilated pupils, drooping eyelids, a bulging eye, and eventually hemorrhage of the blood vessels in the brain, causing convulsions, partial paralysis, and death.

The symptoms of pulmonary mucormycosis include fever and difficulty breathing, with eventual bleeding from the lungs.

The symptoms of gastrointestinal mucormycosis are not unique to the disease, which may complicate diagnosis. Patients typically complain of pressure or pain in the abdomen, nausea, and **vomiting**.

KEY TERMS

Amphotericin B—An antibiotic used to treat mucormycosis and other severe fungal infections.

Opportunistic infection—An infection that develops only when a person's immune system is weakened.

Orbit—The bony cavity or socket surrounding the eye.

Zygomycosis—Another term for mucormycosis. The fungi that cause mucormycosis belong to a group called Zygomycetes.

Diagnosis

Diagnosis is usually based on a combination of the patient's medical history and a visual examination of the nose, throat, and eyes. The doctor will take a tissue sample for biopsy, or a PAS, potassium hydroxide (KOH), or Calcofluor stain in order to make a tentative diagnosis. Confirmation requires a laboratory culture.

Imaging studies are not needed to make the diagnosis. If the patient has mucormycosis, however, **magnetic resonance imaging** (MRI) and **computed tomography scans** (CT scans) will usually show the destruction of soft tissue or bone in patients with advanced disease. Chest x rays will sometimes show a cavity in the lung or an area filled with tissue fluid if the patient has pulmonary mucormycosis.

Treatment

Treatment is usually begun without waiting for laboratory reports because of the rapid spread and high mortality rate of the disease. Therapy includes intravenous amphotericin B (Fungizone); surgical removal of infected tissue; and careful monitoring of the disorder or condition that is responsible for the patient's vulnerability. Most patients who survive require a 4–6-week course of treatment.

Follow-up care includes educating patients about the signs of recurrent mucormycosis—particularly facial swelling and a black discharge from the nose—and telling them to see a doctor at once if they notice these symptoms.

Patients who survive rhinocerebral mucormycosis are often left with severe facial disfigurement and usually require **plastic surgery** to restore their appearance.

Prognosis

The prognosis for recovery from mucormycosis is poor. The mortality rate is 30%–50% of patients with the rhinocerebral form, and even higher for patients with pulmonary mucormycosis. The disease is almost 100% fatal for patients with **AIDS**.

Prevention

Prevention depends on protecting high-risk patients from contact with sugary foods, decaying plants, moldy bread, manure, and other breeding grounds for fungi. In addition, healthcare professionals treating hospital inpatients should be careful to change occlusive dressings frequently and check the underlying skin for any signs of possible fungal infection.

MUGA scan *see* **Multiple-gated acquisition (MUGA) scan**

Multiple-gated acquisition (MUGA) scan

Definition

The multiple-gated acquisition (MUGA) scan is a noninvasive nuclear test that uses the radioactive isotope technetium to evaluate the functioning of the heart's ventricles. It is called multi-gated because a gamma camera takes pictures at specific times during each heartbeat. It is also commonly referred to as a cardiac blood pool scan.

Description

The MUGA scan measures the heart's function and the flow of blood through it. The strongest chamber in the heart is the left ventricle, which serves as the main pump of blood through the body. The left ventricular is assessed by measuring the amount of blood pumped with each heartbeat (the ejection fraction), ventricle filling, and the blood flow into the pumping chamber. A normal ejection fraction is 50% or more. The heart's ejection fraction is one of the most important measures of its performance. The right ventricle's ability to pump blood to the lungs is also assessed, and any abnormalities in the heart wall are identified. The MUGA scan is the most accurate, noninvasive test available to assess the heart's ventricles.

MUGA is a nuclear heart scan, which means that it involves the use of a radioactive isotope that targets the heart and a radionuclide detector that traces the absorption of the radioactive isotope. The isotope is injected into a vein and absorbed by healthy tissue at a known rate during a certain time period. The radionuclide detector, in this case a gamma scintillation camera, picks up the gamma rays emitted by the isotope.

During the MUGA scan, electrodes are placed on the patient's body so that an electrocardiogram (ECG) can be conducted. The imaging equipment and computer are synchronized with the ECG so that images of the heart can be recorded without motion or blur. Then a small amount of the mildly radioactive isotope technetium Tc99m stannous pyrophosphate, usually called technetium, is injected, usually into an arm vein. While the patient lies motionless on the test table, a gamma scintillation camera follows the movement of the technetium through the blood circulating in the heart. The camera, which looks like an x-ray machine and is suspended above the table, moves back and forth over the patient. It displays

WWW.BOOKBAZ.IR

KEY TERMS

Aneurysm—A sac or bulge that forms because of a weak spot in the wall of an artery or heart chamber.

Cardiac shunt—A defect in the wall of the heart that allows blood from different chambers to mix.

Coronary occlusive artery disease—Blockage of the arteries that supply blood to the heart, frequently a precursor to a heart attack.

Ejection fraction—The fraction of all blood in the ventricle that is ejected at each heartbeat. One of the main advantages of the MUGA scan is its ability to measure ejection fraction, one of the most important measures of the heart's performance.

Electrocardiogram (ECG)—A graph that shows the electrical charges that trigger the heart to contract. Heart abnormalities alter the graph, giving clues to the source of the abnormality.

Heart attack—A cardiac emergency that occurs when a clot blocks blood flow in one or more of the heart's arteries. Oxygen supply to the heart muscle is cut off, resulting in the death of heart tissue in the affected area.

Ischemia—A decreased supply of oxygenated blood to a body part or organ, often marked by pain and organ dysfunction, as in ischemic heart disease.

Noninvasive—Describes any procedure that does not penetrate the body.

Radioactive isotope—One of two or more atoms with the same number of protons but a different number of neutrons with a nuclear composition. In nuclear scanning, radioactive isotopes are used as a diagnostic agent.

Technetium—A radioactive isotope frequently used in radionuclide scanning of the heart and other organs. It is produced during nuclear fission reactions.

multiple images of the heart in motion and records them on a computer for later analysis.

The MUGA scan is usually performed in a hospital's nuclear medicine department, but it can also be performed in an outpatient facility or at the patient's bedside if equipment is available. The scan is done immediately after injection of the technetium and usually takes about 30 minutes to one hour. It is also called multigated graft acquisition, multigated acquisition scan, cardiac blood-pool imaging, and equilibrium radionuclide **angiography**. Test results can be affected by patient movement during the test, electrocardiogram abnormalities, an irregular heartbeat, or long-acting nitrates.

The MUGA scan can be done with the patient at rest or exercising (called a **stress** MUGA). The stress MUGA is often performed on patients who have or are suspected of having **coronary artery disease**. The resting MUGA is compared to the stress MUGA, and changes in the heart's pumping performance are analyzed. In some cases, the rest MUGA is compared to a nitroglycerin MUGA, in which the strong heart drug nitroglycerin is administered to the patient before the scan. For the nitroglycerin MUGA, a cardiologist should be present.

The MUGA scan is not dangerous. The technetium is completely gone from the body within a few days of the test. The scan itself exposes the patient to about the same amount of radiation as a chest x ray. The patient can resume normal activities immediately after the test.

Purpose

The MUGA scan is performed to determine if the heart's left and right ventricles are functioning properly and to diagnose abnormalities in the heart wall. It also checks the size of the heart chambers (ventricles), checks the pumping action of the lower ventricles, looks for an abnormality in the wall of the ventricles, such as an aneurysm, and looks for abnormal movement of blood between the heart chambers. It can be ordered in the following patients:

- with known or suspected coronary artery disease, to diagnose the disease and predict outcomes
- with lesions in their heart valves
- who have recently had a heart attack, to assess damage to heart tissue and predict the likelihood of future cardiac events
- with congestive heart failure
- who have undergone percutaneous transluminal coronary angioplasty, coronary artery bypass graft surgery, or medical therapy, to assess the efficacy of the treatment
- with low cardiac output after open-heart surgery
- who are undergoing chemotherapy

Precautions

Pregnant women and those who are **breastfeeding** should not be exposed to technetium. They are the only patients who should not have this scan. However, the accuracy of the results may be affected if the patient moves during imaging, has had other recent nuclear scans, or has an irregular heartbeat.

Aftercare

No aftercare is necessary after a MUGA scan.

Results

If the patient's heart is normal, the technetium will appear to be evenly distributed in the scans. In a stress MUGA, patients with normal hearts exhibit an increase in ejection fraction or no change.

Abnormal results

An uneven distribution of technetium in the heart indicates that the patient has coronary artery disease, a **cardiomyopathy**, or blood shunting within the heart. Abnormalities in a resting MUGA usually indicate a **heart attack**, whereas those that occur during **exercise** usually indicate ischemia. In a stress MUGA, patients with coronary artery disease may exhibit a decrease in ejection fraction.

REVISED BY KARL FINLEY

Multiple chemical sensitivity

Definition

Multiple chemical sensitivity—also known as MCS syndrome, environmental illness, idiopathic environmental intolerance, chemical **AIDS**, total allergy syndrome, or simply MCS—is a disorder in which a person develops symptoms from exposure to chemicals in the environment. With each incidence of exposure, lower levels of the chemical will trigger a reaction and the person becomes increasingly vulnerable to reactions triggered by other chemicals.

Medical experts disagree on the cause of the syndrome, and as to whether MCS is a clinically recognized illness. In a 1992 position statement that remained unchanged as of 2014, the American Medical Association's Council on Scientific Affairs did not recognize MCS as a clinical condition due to a lack of accepted diagnostic criteria and controlled studies on the disorder. Many researchers in Europe as well as the United States regard MCS as a contemporary version of neurasthenia, a concept first introduced by a physician named George Miller Beard in 1869.

Demographics

Because MCS is difficult to diagnose, estimates vary as to what percentage of the population develops MCS. However, most MCS patients are female. The median age of MCS patients is 40 years old, and most experienced symptoms before they were 30 years old. There is also a large percentage of Persian Gulf War veterans who have reported symptoms of chemical sensitivity since their return from the Gulf in the early 1990s.

Description

Multiple chemical sensitivity typically begins with one high-dose exposure to a chemical, but it may also develop with long-term exposure to a low level of a chemical. Chemicals most often connected with MCS include: formaldehyde; pesticides; solvents; petrochemical fuels such as diesel, gasoline, and kerosene; waxes, detergents, and cleaning products; latex; tobacco smoke; perfumes and fragrances; and artificial colors, flavors, and preservatives. People who develop MCS are commonly exposed in one of the following situations: on the job as an industrial worker; residing or working in a poorly ventilated building; or living in conditions of high air or water pollution. Others may be exposed in unique incidents.

WWW.BOOKBAZ.IR

Causes and symptoms

Chemical exposure is often a result of indoor air pollution. Buildings that are tightly sealed for energy conservation may cause a related illness called sick building syndrome, in which people develop symptoms from chronic exposure to airborne environmental chemicals such as formaldehyde from the furniture, carpet glues, and latex caulking. A person moving into a newly constructed building, which has not had time to degas, may experience the initial high-dose exposure that leads to MCS.

As of 2014, the specific biochemical and physiological mechanisms in humans that lead to MCS were not well understood, however, studies suggest that MCS is the end result of four different mechanisms of sensitization acting to reinforce one another. Further research is required to test this hypothesis.

The symptoms of MCS vary from person to person and are not chemical-specific. Symptoms are not limited to one physiological system, but primarily affect the respiratory and nervous systems. Symptoms commonly reported are **headache**, **fatigue**, weakness, difficulty concentrating, short-term **memory loss**, **dizziness**, irritability and depression, **itching**, numbness, burning sensation, congestion, **sore throat**, hoarseness, **shortness of breath**, **cough**, and stomach pains.

One commonly reported symptom of MCS is a heightened sensitivity to odors, including a stronger emotional reaction to them. A Japanese study published in late 2002 reported that patients diagnosed with MCS can identify common odors as accurately as most people, but regard a greater number of them as unpleasant.

One test that has been devised to evaluate patients with MCS is the capsaicin inhalation test. Capsaicin is an alkaloid found in hot peppers that is sometimes used in topical creams and rubs for the treatment of arthritis. When inhaled, capsaicin causes coughing in healthy persons as well as those with **allergies** that affect the airway; however, persons with MCS cough more deeply and frequently than control subjects when given a dose of capsaicin. Although the test is not diagnostic in the strict sense, it has been shown to be an effective way of identifying patients with MCS.

Diagnosis

Multiple chemical sensitivity is a twentieth-century disorder, becoming more prevalent as more human-made chemicals are introduced into the environment in greater quantities. It is especially difficult to diagnose because it presents no consistent or measurable set of symptoms and has no single diagnostic test or marker. For example, a 2002 study of PET scans of MCS patients found no significant functional changes in the patients' brain tissues. Physicians are often either unaware of MCS as a condition, or refuse to accept that MCS exists. They may be unable to diagnose it, or may misdiagnose it as another degenerative disease, or may label it as a psychosomatic illness (a physical illness that is caused by emotional problems). Their lack of understanding generates frustration, **anxiety**, and distrust in patients already struggling with MCS. However, a new specialty of medicine is evolving to address MCS and related illnesses: occupational and environmental medicine. A physician looking for MCS will take a complete patient history and try to identify chemical exposures.

Some MCS patients may be helped by a psychologic evaluation, particularly if they show signs of panic attacks or other **anxiety disorders**. It is known that many patients with MCS suffer from comorbid depression and anxiety. In addition, MCS patients appear to have high rates of **mood disorders** compared to **asthma** patients as well as normal test subjects.

Treatment

While doctors may recommend **antihistamines**, **analgesics**, and other medications to combat the symptoms, the most effective treatment is to avoid those chemicals which trigger the symptoms. This becomes increasingly difficult as the number of offending chemicals increases, and people with MCS often remain at home where they are able to control the chemicals in their environment. This **isolation** often limits their abilities to work and socialize, so supportive counseling may also be appropriate.

Alternatives

Some MCS patients find relief with **detoxification** programs of **exercise** and sweating, and chelation of heavy metals. Others support their health with nutritional regimens and immunotherapy vaccines. Some undergo food-allergy testing and testing for accumulated pesticides in the body to learn more about their condition and what chemicals to avoid. Homeopathy and **acupuncture** can give added support to any treatment program for MCS patients. Botanical medicine can help to support the liver and other involved organs.

Prognosis

Once MCS sets in, sensitivity continues to increase and a person's health continues to deteriorate. Strictly

KEY TERMS

Capsaicin—An alkaloid found in hot peppers that is used in an inhalation test to identify patients with MCS.

Degas—To release and vent gases. New building materials often give off gases and odors and the air should be well circulated to remove them.

Neurasthenia—A term coined in the late nineteenth century to refer to a condition of chronic mental and physical weakness and fatigue. Some researchers regard MCS as a twentieth-century version of neurasthenia.

Sick building syndrome—An illness related to MCS in which a person develops symptoms in response to chronic exposure to airborne environmental chemicals found in a tightly sealed building.

avoiding exposure to triggering chemicals for a year or more may improve health.

Prevention

Multiple chemical sensitivity is difficult to prevent because even at high-dose exposures, different people react differently. Ensuring adequate ventilation in situations with potential for acute high-dose or chronic low-dose chemical exposure, as well as wearing the proper protective equipment in industrial situations, will minimize the risk.

Multiple endocrine adenomatosis
see **Multiple endocrine neoplasia syndromes**

Multiple endocrine neoplasia syndromes

Definition

The multiple endocrine neoplasia (MEN) syndromes are three related disorders affecting the thyroid and other hormonal (endocrine) glands of the body. MEN has previously been known as familial endocrine adenomatosis.

Description

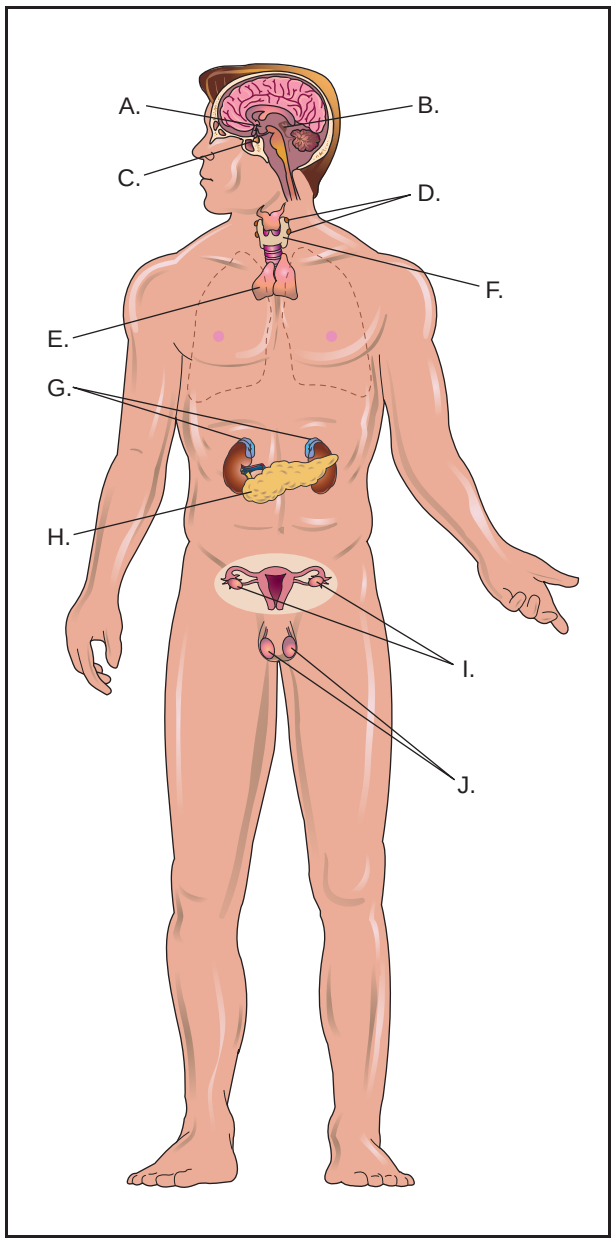
The three forms of MEN are MEN1 (Wermer's syndrome), MEN2A (Sipple syndrome), and MEN2B (previously known as MEN3). Each is an autosomal dominant genetic condition which predisposes to hyperplasia (excessive growth of cells) and tumor formation in a number of endocrine glands.

Causes and symptoms

MEN1 patients experience hyperplasia or tumors of several endocrine glands, including the parathyroids, the pancreas, and the pituitary. The most frequent symptom of MEN1 is **hyperparathyroidism**. Overgrowth of the parathyroid glands leads to over secretion of parathyroid hormone, which leads to elevated blood **calcium** levels, **kidney stones**, weakened bones, and nervous system depression. Almost all MEN1 patients show parathyroid symptoms by age 40.

Tumors of the pancreas known as gastrinomas are also common in MEN1. Excessive secretion of gastrin (a hormone secreted into the stomach to aid in digestion) by these tumors can cause upper gastrointestinal **ulcers**. The anterior pituitary and the adrenal glands can also be affected. Unlike MEN2, the thyroid gland is rarely involved in MEN1 symptoms.

WWW.BOOKBAZ.IR



The human endocrine system: A. Hypothalamus. B. Pineal. C. Pituitary. D. Parathyroid. E. Thymus. F. Thyroid. G. Adrenals. H. Pancreas. I. Ovaries (female). J. Testes (male). *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Patients with MEN2A and MEN2B experience two main symptoms, medullary **thyroid cancer** (MTC) and a tumor of the adrenal gland medulla known as **pheochromocytoma**. MTC is a slow—growing cancer, but one that can be cured in less than 50% of cases. Pheochromocytoma is usually a benign tumor that causes excessive secretion of adrenal hormones, which, in turn, can cause life—threatening **hypertension** and cardiac arrhythmia.

The two forms of MEN2 are distinguished by additional symptoms. MEN2A patients have a predisposition to increase in size (hypertrophy) and to develop tumors of the parathyroid gland. Although similar to MEN1, less than 20% of MEN2A patients show parathyroid involvement.

MEN2B patients show a variety of additional conditions: a characteristic facial appearance with swollen lips; tumors of the mucous membranes of the eye, mouth, tongue, and nasal cavity; enlarged colon; and skeletal abnormalities. Symptoms develop early in life (often under five years of age) in cases of MEN2B and the tumors are more aggressive. MEN2B is about ten—fold less common than MEN2A.

MEN1 is caused by mutation at the PYGM gene. PYGM is one of a group of genes known as tumor suppressor genes. A patient who inherits one defective copy of a tumor suppressor gene from either parent has a strong predisposition to the disease because of the high probability of incurring a second mutation in at least one dividing cell. That cell no longer possesses even one normal copy of the gene. When both copies are defective, tumor suppression fails and tumors develop.

Both types of MEN2 are caused by mutations in another gene, known as RET. A mutation in only one copy of the RET gene is sufficient to cause disease. A number of different mutations can lead to MEN2A, but only one specific genetic alteration leads to MEN2B.

For all types of MEN, the children of an affected individual have a 50% chance of inheriting the defective gene.

Diagnosis

Classical diagnosis of MEN is based on clinical features and on testing for elevated hormone levels. For MEN1, the relevant hormone is parathyroid hormone. For both types of MEN2, the greatest concern is development of medullary thyroid cancer. MTC can be detected by measuring levels of the thyroid hormone, calcitonin. Numerous other hormone levels can be measured to assess the involvement of the various other endocrine glands.

Diagnosis of MEN2B can be made by **physical examination** alone. However, MEN2A shows no distinct physical features and must be identified by measuring hormone levels or by finding endocrine tumors.

KEY TERMS

Endocrine—A term used to describe the glands that produce hormones in the body.

Hyperplasia—An overgrowth of normal cells within an organ or tissue.

Medullary thyroid cancer (MTC)—A slow-growing tumor associated with MEN.

Neoplasm—An abnormal formation of tissue; for example, a tumor.

Pheochromocytoma—A tumor of the medullary of the adrenal gland.

Since 1994, genetic screening using DNA technology has been available for both MEN1 and MEN2. This new methodology allows diagnosis prior to the onset of symptoms.

In the past, there was no way of definitively identifying which children had inherited the defective gene. As a result, all children had to be considered at risk. In the case of MEN2A and MEN2B, children would undergo frequent calcitonin testing. Molecular techniques now allow a positive distinction to be made between children who are and are not actually at risk.

Children who are identified as carriers of the RET gene can be offered total **thyroidectomy** on a preventative (prophylactic) basis to prevent the development of MTC.

Treatment

No comprehensive treatment is available for genetic conditions such as MEN. However, some of the consequences of MEN can be symptomatically treated.

Pheochromocytoma in both types of MEN 2 can be cured by surgical removal of this slow growing tumor.

Treatment of MTC is by surgical removal of the thyroid, although doctors may disagree at what stage to remove the thyroid. After thyroidectomy, the patient will receive normal levels of thyroid hormone orally or by injection.

Even when surgery is performed early, metastatic spread of the cancer may have already occurred. Since this cancer is slow growing, metastasis may not be obvious. Metastasis is very serious in MTC because **chemotherapy** and **radiation therapy** are not effective in controlling its spread.

Prognosis

Diagnosed early, the prognosis for the MEN diseases is reasonably good, even for MEN2B, the most dangerous of the three forms. Even in the absence of treatment, a few individuals with MEN2A mutations will never show any symptoms at all. Analysis of at—risk family members using molecular genetic techniques will lead to earlier treatment and improved outcomes.

Prevention

One of the most serious consequences of MEN is MTC, which can be prevented by thyroidectomy. There is no preventive measure to block the occurrence of genetic mutations such as those that cause MEN.

Multiple marker test

Definition

The multiple marker test, sometimes called a quad screen, is a blood test offered to pregnant women during the fifteenth to twentieth week of **pregnancy** to help identify if the unborn baby is at risk for **birth defects**.

WWW.BOOKBAZ.IR

Description

Before 1964, when the association between low levels of AFP and an increased risk for **Down syndrome** was reported, risk assessment for chromosomal diseases was based upon maternal age. At age 35, the risk of carrying a Down syndrome fetus is approximately 1 in 270, and this was deemed sufficient to warrant **amniocentesis**, a more accurate but invasive test that involves using a needle to draw out a sample of the embryonic fluid that surrounds the fetus. However, 3 of 4 Down syndrome fetuses occur in women under 35 years old. When AFP testing was used along with maternal age, the rate of detection of Down syndrome increased to about 45%, but this level of sensitivity did not justify the use of amniocentesis in younger women because of the increased risk of **miscarriage**. The inclusion of uE3 and hCG testing improved the detection rate for Down syndrome to between 65% and 80% for all age groups. The multiple marker test is relatively inexpensive and is covered by most insurance plans.

Purpose

Researchers found that women carrying a fetus at risk for a variety of disorders, including neural tube deficits and chromosomal abnormalities, tend to have abnormal levels of certain substances in their blood. These substances include alpha-fetoprotein (AFP), a protein produced by the fetus; unconjugated estriol (uE3), a hormone manufactured by both the fetus and the placenta; human chorionic gonadotropin (hCG), a hormone produced in the placenta; and inhibit-A, also produced by the placenta. The quantities of these four substances present, along with other characteristics of the mother, such as her age, can be used to help determine whether the fetus is at an increased risk of being born with certain abnormalities. One of the most common of these is Down syndrome, a condition that includes mental retardation, skeletal abnormalities such as **cleft palate**, and organ abnormalities such as **heart disease** and intestinal obstruction. In some cases only AFP, uE3, and hCG are screened for, in which case the test is called a triple-screen test.

Measuring the levels of these four proteins helps healthcare workers determine whether the risk for a specific pregnancy is different from that for the general population of pregnant women of the same age. For example, the average 25-year-old woman has one chance in a 1,000 of bearing a Down syndrome baby. After her blood is analyzed for the four proteins, her specific risk can be evaluated. It could be considerably lower or higher than the average risk. This could help her make decisions about her pregnancy and plan for the future of her child.

The multiple marker test was originally intended to detect fetuses at high risk for Down syndrome, an abnormality that comes about when, at fertilization, the embryo receives three copies of chromosome 21 instead of the usual two. For unknown reasons, extra amounts of genetic material are usually associated with severe developmental defects. Although Down syndrome is the most common such disorder, it is by no means the only one. Chromosomes 13 or 18 can also turn up as a triple set (or trisomy). An abnormal pattern of the four proteins may signal one of these trisomies or a neural tube defect such as **spina bifida**.

Precautions

It is important that the correct age of the fetus be determined by last menstrual period dating and recorded for the risk calculation. Errors in determining the age of the fetus lead to errors when interpreting the test results. Since the multiple marker test is only a screening tool, an abnormal test result is not a positive diagnosis of a birth defect. Accurate dating of the fetus lowers the false-positive and false-negative rates associated with this screening test. Other factors such as whether the mother is carrying multiple fetuses and if she has diabetes must be taken into consideration for an accurate result.

Preparation

There is no specific physical preparation for this test. **Fasting** is not required.

Aftercare

After the blood sample is drawn, pressure should be applied to the puncture site until the bleeding stops to reduce bruising. A bandage or taped ball of cotton may be applied to the site. A warm pack may be applied to the site to relieve discomfort.

Results

The level of each substance is assessed and then divided by the median concentration of that substance for the given week of pregnancy to generate a multiple of the median value (MOM). Results are expressed as multiples of the median value used by the laboratory. Normal ranges expressed in concentration (for example, ng/mL) are dependent upon the age of the fetus, but MOM values are age-adjusted and do not change. These values are used to calculate risk. If the multiple

KEY TERMS

Amniocentesis—A test performed to determine the health, sex, or genetic constitution of a fetus by taking a sample of amniotic fluid through a needle inserted into the womb of the mother.

Amniotic fluid—The fluid that surrounds a fetus while it is developing. It is the fluid that flows out when the mother's water breaks before a baby is born.

Down syndrome—The most prevalent of a class of genetic defects known as trisomies, in which cells contain three copies of certain chromosomes rather than the usual two. Down syndrome, or trisomy 21, usually results from three copies of chromosome 21. The disorder is characterized by a broad skull, blunt facial features, short stature, and learning difficulties and mental retardation, as well as increased susceptibility to a variety of health problems.

Placenta—An organ that develops inside the uterus of pregnant women to supply food and oxygen to the fetus through the umbilical cord.

of the median value is below 2.0 MOM or 2.5 MOM (depending on the laboratory), the fetus is considered to be at a lower risk for a genetic defect.

Abnormal results

If the multiple of the median value is above 2.0 MOM or 2.5 MOM (depending on the laboratory), the fetus is considered to be at a higher risk for a genetic defect. In additional testing, the MOM value for amniotic fluid is used to calculate the exact probability the fetus is affected (1:100, for example). With respect to Down syndrome and trisomy 18, the MOM values are also used in the calculation of probability. The woman is considered to be high risk or screen positive for Down syndrome if the risk is greater than the standard risk for women who are 35 years old or older (one in 270). For trisomy 18, the cut-off is one in 150.

Risks

The complications associated with drawing blood are minimal but may include bleeding from the puncture site, feeling faint or lightheaded after the blood is drawn, or blood accumulating under the puncture site (hematoma). There are some psychological risks to a false-positive test result, in that the mother may experience significant **stress** as she awaits the results of additional tests.

Multiple myeloma

Definition

Multiple myeloma is a cancer in which antibody-producing plasma cells grow in an uncontrolled and invasive (malignant) manner.

Description

Multiple myeloma, also known as plasma cell myeloma, is the second-most common cancer of the blood. It is the most common type of plasma cell neoplasm. Multiple myeloma accounts for approximately 1% of all cancers and 2% of all deaths from cancer. Multiple myeloma is a disease in which malignant plasma cells spread through the bone marrow and hard outer portions of the large bones of the body.

This x ray of the patient's left clavicle indicates an occurrence of myelomas in the bone. *(Custom Medical Stock Photo, Inc.)*

These myeloma cells may form tumors called plasmacytomas. Eventually, multiple soft spots or holes, called osteolytic lesions, form in the bones.

Bone marrow is the spongy tissue within the bones. The breastbone, spine, ribs, skull, pelvic bones, and the long bone of the thigh all are particularly rich in marrow. Bone marrow is a very active tissue that is responsible for producing the cells that circulate in the blood. These include the red blood cells that carry oxygen, the white blood cells that develop into immune system cells, and platelets, which cause blood to clot.

Plasma cells and immunoglobulins

Plasma cells develop from B-lymphocytes or B-cells, a type of white blood cell. B-cells, like all blood cells, develop from unspecialized stem cells in the bone marrow. Each B-cell carries a specific antibody that recognizes a specific foreign substance called an antigen. Antibodies are large proteins called immunoglobulins (Igs), which recognize and destroy foreign substances and organisms such as bacteria. When a B-cell encounters its antigen, it begins to divide rapidly to form mature plasma cells. These plasma cells are all identical (monoclonal). They produce large amounts of identical antibody that are specific for the antigen.

Malignant plasma cells

Multiple myeloma begins when the genetic material (DNA) is damaged during the development of a stem cell into a B-cell in the bone marrow. This causes the cell to develop into an abnormal or malignant plasmablast, a developmentally early form of plasma cell. Plasmablasts produce adhesive molecules that allow them to bond to the inside of the bone marrow. A growth factor, called interleukin-6, promotes uncontrolled growth of these myeloma cells in the bone marrow and prevents their natural death. Whereas normal bone marrow contains less than 5% plasma cells, bone marrow of an individual with multiple myeloma contains over 10% plasma cells.

In most cases of multiple myeloma, the malignant plasma cells all make an identical Ig. Igs are made up of four protein chains that are bonded together. Two of the chains are light and two are heavy. There are five classes of heavy chains, corresponding to five types of Igs with different immune system functions. The Igs from myeloma cells are nonfunctional and are called paraproteins. All of the paraproteins from any one individual are

monoclonal (identical) because the myeloma cells are identical clones of a single plasma cell. Thus, the paraprotein is a monoclonal protein or M-protein. The M-proteins crowd out the functional Igs and other components of the immune system. They also cause functional antibodies, which are produced by normal plasma cells, to rapidly break down. Thus, multiple myeloma depresses the immune system.

In about 75% of multiple myeloma cases, the malignant plasma cells also produce monoclonal light chains, or incomplete Igs. These are called Bence-Jones proteins and are secreted in the urine. Approximately 1% of multiple myelomas are called nonsecretors because they do not produce any abnormal Ig.

Osteolytic lesions

About 70% of individuals with multiple myeloma have soft spots or lesions in their bones. These lesions can vary from quite small to grapefruit-size. In part, these lesions occur because the malignant plasma cells rapidly outgrow the normal bone-forming cells. In addition, malignant myeloma cells produce factors that affect cells called osteoclasts. These are the cells that normally destroy old bone, so that new bone can be produced by cells called osteoblasts. The myeloma cell factors increase both the activation and the growth of osteoclasts. As the osteoclasts multiply and migrate, they destroy healthy bone and create lesions. **Osteoporosis**, or widespread bone weakness, may develop.

There are more than 40,000 multiple myeloma patients in the United States. The American Cancer Society predicts an additional 14,400 new cases in 2001. About 11,200 Americans will die of the disease in 2001. Multiple myeloma is one of the leading causes of cancer deaths among African Americans.

In Western industrialized countries, approximately four people in 100,000 develop multiple myeloma. The incidence of multiple myeloma among African Americans is 9.5 per 100,000, about twice that of Caucasians. Asians have a much lower incidence of the disease. In China, for example, the incidence of multiple myeloma is only one in 100,000. The offspring and siblings of individuals with multiple myeloma are at a slightly increased risk for the disease.

At diagnosis, the average age of a multiple myeloma patient is 68 to 70. Although the average age at onset is decreasing, most multiple myelomas still occur in people over 40. This cancer is somewhat more prevalent in men than in women.

Causes and symptoms

Associations

The cause of multiple myeloma has not been determined. However, a number of possible associations have been identified:

- decreased immune system function; the immune systems of older individuals may be less efficient at detecting and destroying cancer cells
- genetic (hereditary) factors, suggested by the increased incidence in some ethnic groups and among family members
- occupational factors, suggested by the increased incidence among agricultural, petroleum, wood, and leather workers, and cosmetologists
- long-term exposure to herbicides, pesticides, petroleum products, heavy metals, plastics, and dusts such as asbestos
- radiation exposure, as among Japanese atomic bomb survivors, nuclear weapons workers, and medical personnel such as radiologists
- Kaposi's sarcoma-associated herpes virus (also called human herpes virus-8 or HHV-8), found in the blood and bone marrow cells of many multiple myeloma patients

Early symptoms

The accumulation of malignant plasma cells can result in tiny cracks or **fractures** in bones. Malignant plasma cells in the bone marrow can suppress the formation of red and white blood cells and platelets. About 80% of individuals with multiple myeloma are anemic due to low red blood cell formation. Low white blood cell formation results in increased susceptibility to infection, since new, functional antibodies are not produced. In addition, normal circulating antibodies are rapidly destroyed. Low platelet formation can result in poor blood clotting. It is rare, however, that insufficient white blood cell and platelet formations are presenting signs of multiple myeloma.

These factors cause the early symptoms of multiple myeloma:

- pain in the lower back or ribs
- fatigue and paleness due to anemia (low red blood cell count)
- frequent and recurring infections, including bacterial pneumonia, urinary-tract and kidney infections, and shingles
- bleeding

WWW.BOOKBAZ.IR

Bone destruction

Bone **pain**, particularly in the backbone, hips, and skull, is often the first symptom of multiple myeloma. As malignant plasma cells increase in the bone marrow, replacing normal marrow, they exert pressure on the bone. As overly active osteoclasts (large cells responsible for the breakdown of bone) remove bone tissue, the bone becomes soft. Fracture and spinal cord compression may occur.

Plasmacytomas (malignant tumors of plasma cells) may weaken bones, causing fractures. Fractured bones or weak or collapsed spinal bones, in turn, may place unusual pressure on nearby nerves, resulting in nerve pain, burning, or numbness and muscle weakness. Proteins produced by myeloma cells also may damage nerves.

Calcium from the destroyed bone enters the blood and urine, causing **hypercalcemia**, a medical condition in which abnormally high concentrations of calcium compounds exist in the bloodstream. High calcium affects nerve cell and kidney function. The symptoms of hypercalcemia include:

- weakness and fatigue
- depression
- mental confusion
- constipation
- increased thirst
- increased urination
- nausea and vomiting
- kidney pain
- kidney failure

Hypercalcemia affects about one-third of multiple myeloma patients.

Serum proteins

The accumulation of M-proteins in the serum (the liquid portion of the blood) may cause additional complications, such as hyperviscosity syndrome, or thickening of the blood (though rare in multiple myeloma patients). Symptoms of hyperviscosity include:

- fatigue
- headaches
- shortness of breath
- mental confusion
- chest pain
- kidney damage and failure
- vision problems
- Raynaud's phenomenon

Poor blood circulation, or Raynaud's phenomenon, can affect any part of the body, but particularly the fingers, toes, nose, and ears.

Cryoglobulinemia occurs when the protein in the blood forms particles under cold conditions. These particles can block small blood vessels and cause pain and numbness in the toes, fingers, and other extremities during cold weather.

Amyloidosis is a rare complication of multiple myeloma. It usually occurs in individuals whose plasma cells produce only Ig light chains. These Bence-Jones proteins combine with other serum proteins to form amyloid protein. This starchy substance can invade tissues, organs, and blood vessels. In particular, amyloid proteins can accumulate in the kidneys, where they block the tiny tubules that are the kidney's filtering system. Indicators of amyloidosis include:

- carpal tunnel syndrome
- kidney failure
- liver failure
- heart failure

Diagnosis

Blood and urine tests

Often, the original diagnosis of multiple myeloma is made from routine blood tests that are performed for other reasons. Blood tests may indicate:

- anemia
- abnormal red blood cells
- high serum protein levels
- how levels of normal antibody
- high calcium levels
- high blood urea nitrogen (BUN) levels
- high creatinine levels

Urea and creatinine normally are excreted in the urine. High levels of urea and creatinine in the blood indicate that the kidneys are not functioning properly to eliminate these substances.

Protein electrophoresis is a laboratory technique that uses an electrical current to separate the different proteins in the blood and urine on the basis of size and charge. Since all of the multiple myeloma M-proteins in the blood and urine are identical, electrophoresis of blood and urine from a patient with multiple myeloma shows a large M-protein spike, corresponding to the high concentration of monoclonal Ig. Electrophoresis of the urine also can detect Bence-Jones proteins.

Bones

A bone marrow aspiration utilizes a very thin, long needle to remove a sample of marrow from the hip bone. Alternatively, a bone marrow biopsy with a larger needle removes solid marrow tissue. The marrow is examined under the microscope for plasma cells and tumors. If 10% to 30% of the cells are plasma cells, multiple myeloma is the usual diagnosis.

X rays are used to detect osteoporosis, osteolytic lesions, and fractures. Computer-assisted tomography (CAT or CT) scans can detect lesions in both bone and soft tissue. **Magnetic resonance imaging** (MRI) may give a more detailed image of a certain bone or a region of the body.

Treatment

Related disorders

Monoclonal gammopathy of undetermined significance (MGUS) is a common condition in which a monoclonal Ig is detectable. However, there are no tumors or other symptoms of multiple myeloma. MGUS occurs in about 1% of the general population and in about 3% of those over age 70. Over a period of years, about 16% to 20% of those with MGUS will develop multiple myeloma or a related cancer called malignant lymphoma.

Occasionally, only a single plasmacytoma develops, either in the bone marrow (isolated plasmacytoma of the bone) or other tissues or organs (extramedullary plasmacytoma). Some individuals with solitary plasmacytoma may develop multiple myeloma.

Clinical stages

The Durie-Salmon system is used to stage multiple myeloma. Stage I multiple myeloma requires all of the following (1 gram = approx. 0.02 pints, 1 deciliter = approx. 0.33 ounces):

- hemoglobin (the oxygen-transporting molecule of red blood cells) above 10 grams/deciliter (g/dl)
- serum calcium below 12 mg/dl
- normal bone structure or only isolated plasmacytoma
- low M-protein, based on established guideline levels of Ig protein chains

Approximately 5% of multiple myeloma cases are not progressing at diagnosis, and may not progress for months or years. This is called smoldering myeloma. These patients have stage I blood chemistry but no symptoms.

Stage II multiple myeloma fits neither stage I nor stage III. Stage III multiple myeloma meets one or more the following criteria:

- hemoglobin below 8.5 g/dl
- serum calcium above 12 mg/dl
- advanced bone lesions
- high M-protein

Each stage is subclassified as A or B, based on serum creatinine indicators of normal or abnormal kidney function. Most patients have stage III multiple myeloma at diagnosis.

Prognostic indicators

Prognostic indicators for multiple myeloma may be used instead of, or in addition to, the staging system described above. Prognostic indicators are laboratory tests that help to define the stage of the disease at diagnosis, and its progression during treatment. These indicators are:

- plasmablastic multiple myeloma (presence of plasmablasts, the precursor malignant plasma cells)
- plasma cell labeling index (the percentage of plasma cells that are actively dividing)
- beta 2-microglobulin, a protein secreted by B-cells that correlates with the myeloma cell mass (also indicates kidney damage)

Since multiple myeloma often progresses slowly, and since the treatments can be toxic, the disease may not be treated until M-protein levels in the blood are quite high. In particular, MGUS and smoldering myeloma may be followed closely but not treated. Solitary plasmacytomas are treated with radiation and/or surgery and followed closely with examinations and laboratory tests.

Chemotherapy

Chemotherapy, or treatment with anti-cancer drugs, is used for multiple myeloma. MP, a combination of the drugs melphalan and prednisone, is the standard treatment. Usually, the drugs are taken by mouth every 3 to 4 weeks for 6 to 9 months or longer, until the M-protein levels in the blood stop decreasing. MP usually results in a 50% reduction in M-protein.

Dexamethasone, a corticosteroid, sometimes is used to treat the elderly or those in poor health. It can drop the M-protein levels by 40% in untreated individuals and by 20% to 40% in patients who have not responded to previous treatment. Other chemotherapy drugs, including cyclophosphamide, carmustine, doxorubicin, vincristine, and chlorambucil, may be used as well.

WWW.BOOKBAZ.IR

Multiple myeloma usually recurs within a year after the end of chemotherapy. Although the chemotherapy can be repeated after each recurrence, it is progressively less responsive to treatment.

Side effects of chemotherapy may include:

- anemia
- hair loss
- nausea
- vomiting
- diarrhea
- mood swings
- swelling
- acne

These side effects disappear after treatment is discontinued.

Other drug treatments

Bisphosphonates are drugs that inhibit the activity of osteoclasts. These drugs can slow the progression of bone disease, reduce pain, and help prevent bone fractures. Different types of bisphosphonates inhibit osteoclasts in different ways. They also reduce the production of interleukin-6 by bone marrow cells. Laboratory studies suggest that bisphosphonates may kill or inhibit the growth of multiple myeloma cells. Pamidronate is the most common bisphosphonate for treating multiple myeloma.

The drug thalidomide appears to have several anti-myeloma activities. Thalidomide affects the immune system in various ways and it appears to inhibit myeloma cells, both directly and indirectly. It also inhibits the growth of new blood vessels that are needed by tumors. However, if thalidomide is taken during **pregnancy**, it can cause severe **birth defects** or death of the fetus.

The drug allopurinol may be used to reduce high blood levels of uric acid that result from kidney dysfunction. **Diuretics** can improve kidney function. Infections require prompt treatment with **antibiotics**.

BONE AND PERIPHERAL BLOOD STEM CELL TRANSPLANTATION. Bone marrow or peripheral blood stem cell transplantations (PBSCT) are used to replace the stem cells of the bone marrow following high-dosage chemotherapy. Chemotherapy destroys the bone marrow stem cells that are necessary to produce new blood cells. In an autologous transplant, the patient's bone marrow stem cells or peripheral blood stem cells (immature bone marrow cells found in the blood) are collected, treated with drugs to kill any myeloma cells, and frozen prior to chemotherapy. Growth factors are used to increase the number of peripheral stem cells prior to collection. A procedure called apheresis is used to collect the peripheral stem cells. Following high-dosage chemotherapy, the stem cells are injected into the individual. In an allogeneic transplant, the donor stem cells come from a genetically related individual such as a sibling.

Other treatments

Blood transfusions may be required to treat severe anemia.

Plasmapheresis, or plasma exchange **transfusion**, may be used to thin the blood to treat hyperviscosity syndrome. In this treatment, blood is removed and passed through a machine that separates the plasma, containing the M-protein, from the red and white blood cells and platelets. The blood cells are transfused back into the patient, along with a plasma substitute or donated plasma.

Multiple myeloma may be treated with high-energy x rays directed at a specific region of the body. **Radiation therapy** is used for treating bone pain.

Alternatives

Interferon alpha, an immune-defense protein that is produced by some white blood cells and bone marrow cells, can slow the growth of myeloma cells. It usually is given to patients following chemotherapy, to prolong their remission. However, interferon may have toxic effects in older individuals with multiple myeloma.

Once multiple myeloma is in remission, calcium and **vitamin D** supplements can improve bone density. It is important not to take these supplements when the myeloma is active. Individuals with multiple myeloma must drink large amounts of fluid to counter the effects of hyperviscous blood.

Prognosis

The prognosis for individuals with MGUS or solitary plasmacytoma is very good. Most do not develop multiple myeloma. However, approximately 15% of all patients with multiple myeloma die within three months of diagnosis. About 60% respond to treatment and live for an average of two and a half to three years following diagnosis. Approximately 23% of patients die of other illnesses associated with advanced age.

The prognosis for a given individual may be based on the prognostic indicators described above. The median survival for those without plasmablasts, and

KEY TERMS

Amyloidosis—A complication of multiple myeloma in which amyloid protein accumulates in the kidneys and other organs, tissues, and blood vessels.

Anemia—Any condition in which the red blood cell count is below normal.

Antibody—Immunoglobulin produced by immune system cells that recognizes and binds to a specific foreign substance (antigen).

Antigen—Foreign substance that is recognized by a specific antibody.

B-cell (B-lymphocyte)—Type of white blood cell that produces antibodies.

Bence-Jones protein—Light chain of an immunoglobulin that is overproduced in multiple myeloma and is excreted in the urine.

Beta 2-microglobulin—Protein produced by B-cells; high concentrations in the blood are indicative of multiple myeloma.

Cryoglobulinemia—Condition in which protein in the blood forms particles in the cold, blocking blood vessels, leading to pain and numbness of the extremities.

Electrophoresis—Use of an electrical field to separate proteins in a mixture (such as blood or urine), on the basis of the size and electrical charge of the proteins.

Hemoglobin—Protein in red blood cells that carries oxygen.

Hypercalcemia—Abnormally high levels of calcium in the blood.

Hyperviscosity—Thick, viscous blood, caused by the accumulation of large proteins, such as immunoglobulins, in the serum.

Immunoglobulin (Ig)—Antibody; large protein produced by B-cells that recognizes and binds to a specific antigen.

M-protein—Monoclonal or myeloma protein; paraprotein; abnormal antibody found in large amounts in the blood and urine of individuals with multiple myeloma.

Malignant—A characteristic of cancer cells that grow uncontrollably and invade other tissues.

Monoclonal—Identical cells or proteins; cells (clones) derived from a single, genetically distinct cell, or proteins produced by these cells.

Monoclonal gammopathy of undetermined significance (MGUS)—Common condition in which M-protein is present, but there are no tumors or other symptoms of disease.

Neoplasm—Tumor made up of cancer cells.

Osteoblast—Bone-forming cell.

Osteoclast—Cell that absorbs bone.

Osteolytic lesion—Soft spot or hole in bone caused by cancer cells.

Osteoporosis—Condition in which the bones become weak and porous, due to loss of calcium and destruction of cells.

Paraprotein—M-protein; abnormal immunoglobulin produced in multiple myeloma.

Plasma cell—Type of white blood cell that produces antibodies; derived from an antigen-specific B-cell.

Platelet—Cell that is involved in blood clotting.

Stem cell—Undifferentiated cell that retains the ability to develop into any one of numerous cell types.

with a low plasma cell labeling index (PCLI) and low beta 2-microglobulin, is 5.5 years. The median survival for patients with plasmablastic multiple myeloma, or with a high PCLI (1% or greater) and high beta 2-microglobulin (4 or higher), is 1.9 and 2.4 years, respectively. Many multiple myeloma patients are missing part or all of chromosome 13. The deletion of this chromosome, along with high beta 2-microglobulin, leads to a poor prognosis.

With treatment, multiple myeloma may go into complete remission. This is defined as:

- M-protein absent from the blood and urine
- myeloma cells not detectable in the bone marrow
- no clinical symptoms
- negative laboratory tests

However, with very sensitive testing, a few myeloma cells are usually detectable and eventually lead to a recurrence of the disease, in the bone or elsewhere in the body.

Prevention

There are no clearly established risk factors for multiple myeloma, and it is possible that a combination

WWW.BOOKBAZ.IR

of factors interact to cause the disease. Thus, there is no method for preventing multiple myeloma.

Margaret Alic, Ph.D.

Multiple personality disorder

Definition

Multiple personality disorder, or MPD, is a mental disturbance classified as one of the **dissociative disorders** in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM–IV*). It has been renamed dissociative identity disorder (DID). MPD or DID is defined as a condition in which "two or more distinct identities or personality states" alternate in controlling the patient's consciousness and behavior. It is worth noting that *split personality* is not an accurate term for DID and should not be used as a synonym for **schizophrenia**.

Description

The precise nature of DID (MPD) as well as its relationship to other mental disorders is still a subject of debate. Some researchers think that DID may be a relatively recent development in western society. It may be a culture–specific syndrome found in western society, caused primarily by both childhood **abuse** and unspecified long–term societal changes. Unlike depression or **anxiety disorders**, which have been recognized, in some form, for centuries, the earliest cases of persons reporting DID symptoms were not recorded until the 1790s. Most were considered medical oddities or curiosities until the late 1970s, when increasing numbers of cases were reported in the United States. Psychiatrists are still debating whether DID was previously misdiagnosed and underreported, or whether it is currently overdiagnosed. Because childhood **trauma** is a factor in the development of DID, some doctors think it may be a variation of post-traumatic **stress** disorder (PTSD). DID and PTSD are conditions in which dissociation is a prominent mechanism. The female-to-male ratio for DID is about 9:1, but the reasons for the gender imbalance are unclear. Some experts have attributed the imbalance in reported cases to higher rates of abuse of female children, and some to the possibility that males with DID are underreported because they might be in prison for violent crimes.

The most distinctive feature of DID is the formation and emergence of alternate personality states, or "alters." Patients with DID experience their alters as distinctive individuals possessing different names, histories, and personality traits. It is not unusual for DID patients to have alters of different genders, sexual orientations, ages, or nationalities. Some patients have been reported with alters that are not even human; alters have been animals or even aliens from outer space. The typical DID patient has between two and 10 alters, but some have been reported with over one hundred.

Causes and symptoms

The severe dissociation that characterizes patients with DID is currently understood to result from a set of causes:

- An innate ability to dissociate easily
- Repeated episodes of severe physical or sexual abuse in childhood
- The lack of a supportive or comforting person to counteract abusive relative(s)

- The influence of other relatives with dissociative symptoms or disorders

The relationship of dissociative disorders to childhood abuse has led to intense controversy and lawsuits concerning the accuracy of childhood memories. The brain's storage, retrieval, and interpretation of childhood memories are still not fully understood.

The major dissociative symptoms experienced by DID patients are **amnesia**, depersonalization, derealization, and identity disturbances.

Amnesia

Amnesia in DID is marked by gaps in patients' memory for long periods of their past, in some cases, their entire childhood. Most DID patients have amnesia, or "lost time," for periods when another personality is "out." They may report finding items in their house that they cannot remember having purchased, finding notes written in different handwriting, or other evidence of unexplained activity.

Depersonalization

Depersonalization is a dissociative symptom in which patients feel that their body is unreal, is changing, or is dissolving. Some DID patients experience depersonalization as feeling outside of their body or as watching a movie of themselves.

Derealization

Derealization is a dissociative symptom in which the patient perceives the external environment as unreal. Patients may see walls, buildings, or other objects as changing in shape, size, or color. DID patients may fail to recognize relatives or close friends.

Identity disturbances

Identity disturbances in DID result from the patient's having split off entire personality traits or characteristics as well as memories. When a stressful or traumatic experience triggers the reemergence of these dissociated parts, the patient switches—usually within seconds—into an alternate personality. Some patients have histories of erratic performance in school or in their jobs caused by the emergence of alternate personalities during examinations or other stressful situations. Patients vary with regard to their alters' awareness of one another.

Diagnosis

The diagnosis of DID is complex and some physicians believe it is often missed, while others feel it is overdiagnosed. Patients have been known to have been treated under a variety of other psychiatric diagnoses for a long time before being rediagnosed with DID. The average DID patient is in the mental health-care system for six to seven years before being diagnosed as a person with DID. Many DID patients are misdiagnosed as depressed because the primary or "core" personality is subdued and withdrawn, particularly in female patients. However, some core personalities, or alters, may genuinely be depressed, and may benefit from antidepressant medications. One reason misdiagnoses are common is that DID patients may truly meet the criteria for **panic disorder** or somatization disorder.

Misdiagnoses include schizophrenia, **borderline personality disorder**, and, as noted, somatization disorder and panic disorder. DID patients are often frightened by their dissociative experiences, which can include losing awareness of hours or even days of time, meeting people who claim to know them by another name, or feeling "out of body." Persons with the disorder may go to emergency rooms or clinics because they fear they are going insane.

When evaluating a patient for DID, the doctor will first rule out physical conditions that sometimes produce amnesia, depersonalization, or derealization. These conditions include head injuries; brain disease, especially seizure disorders; side effects from medications; substance abuse or intoxication; AIDS–dementia complex; or recent periods of extreme physical stress and sleeplessness. In some cases, the doctor may give the patient an electroencephalograph (EEG) to exclude **epilepsy** or other seizure disorders. The physician also must consider whether the patient is **malingering** and/or offering fictitious complaints.

If the patient appears to be physically normal, the doctor will next rule out psychotic disturbances, including schizophrenia. Many patients with DID are misdiagnosed as schizophrenic because they may hear their alters talking inside their heads. If the doctor suspects DID, he or she can use a screening test called the Dissociative Experiences Scale (DES). If the patient has a high score on this test, he or she can be evaluated further with the Dissociative Disorders Interview Schedule (DDIS) or the Structured Clinical Interview for *DSM–IV* Dissociative Disorders (SCID–D). The doctor may also use the Hypnotic Induction Profile (HIP) or a similar test of the patient's hypnotizability.

Treatment

Treatment of DID may last for five to seven years in adults and usually requires several different treatment methods.

WWW.BOOKBAZ.IR

KEY TERMS

Alter—An alternate or secondary personality in a patient with DID.

Amnesia—A general medical term for loss of memory that is not due to ordinary forgetfulness. Amnesia can be caused by head injuries, brain disease, or epilepsy as well as by dissociation.

Depersonalization—A dissociative symptom in which the patient feels that his or her body is unreal, is changing, or is dissolving.

Derealization—A dissociative symptom in which the external environment is perceived as unreal.

Dissociation—A psychological mechanism that allows the mind to split off traumatic memories or disturbing ideas from conscious awareness.

Dissociative identity disorder (DID)—Term that replaced multiple personality disorder (MPD). A condition in which two or more distinctive identities or personality states alternate in controlling a person's consciousness and behavior.

Hypnosis—An induced trance state used to treat the amnesia and identity disturbances that occur in dissociative identity disorder (DID).

Multiple personality disorder (MPD)—The former, though often still used, term for dissociative identity disorder (DID).

Primary personality—The core personality of an DID patient. In women, the primary personality is often timid and passive and may be diagnosed as depressed.

Psychotherapy—The treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

Trauma—A disastrous or life-threatening event that can cause severe emotional distress. DID is associated with trauma in a person's early life or adult experience.

Psychotherapy

Ideally, patients with DID should be treated by a therapist with specialized training in dissociation. This specialized training is important because the patient's personality switches can be confusing or startling. In addition, many patients with DID have hostile or suicidal alter personalities. Most therapists who treat DID patients have rules or contracts for treatment that include such issues as the patient's responsibility for his or her safety. **Psychotherapy** for DID patients typically has several stages: an initial phase for uncovering and "mapping" the patient's alters; a phase of treating the traumatic memories and "fusing" the alters; and a phase of consolidating the patient's newly integrated personality.

Most therapists who treat multiples, or DID patients, recommend further treatment after personality integration, on the grounds that the patient has not learned the social skills that most people acquire in adolescence and early adult life. In addition, **family therapy** is often recommended to help the patient's family understand DID and the changes that occur during personality reintegration.

Many DID patients are helped by group as well as individual treatment, provided that the group is limited to people with dissociative disorders. DID patients sometimes have setbacks in mixed therapy groups because other patients are bothered or frightened by their personality switches.

Medications

Some doctors will prescribe tranquilizers or antidepressants for DID patients because their alter personalities may have **anxiety** or **mood disorders**. However, other therapists who treat DID patients prefer to keep medications to a minimum because these patients can easily become psychologically dependent on drugs. In addition, many DID patients have at least one alter who abuses drugs or alcohol, substances which are dangerous in combination with most tranquilizers.

Hypnosis

While not always necessary, hypnosis is a standard method of treatment for DID patients. Hypnosis may help patients recover repressed ideas and memories. Further, hypnosis can also be used to control problematic behaviors that many DID patients exhibit, such as self-mutilation, or **eating disorders** like **bulimia nervosa**. In the later stages of treatment, the therapist may use hypnosis to "fuse" the alters as part of the patient's personality integration process.

Alternatives

Alternative treatments that help to relax the body are often recommended for DID patients as an adjunct to psychotherapy and/or medication. These treatments include **hydrotherapy**, botanical medicine (primarily herbs that help the nervous

system), therapeutic massage, and **yoga**. Homeopathic treatment can also be effective for some people. **Art therapy** and the keeping of journals are often recommended as ways that patients can integrate their past into their present life. **Meditation** is usually discouraged until the patient's personality has been reintegrated.

Prognosis

Some therapists believe that the prognosis for recovery is excellent for children and good for most adults. Although treatment takes several years, it is often ultimately effective. As a general rule, the earlier the patient is diagnosed and properly treated, the better the prognosis.

Prevention

Prevention of DID requires intervention in abusive families and treating children with dissociative symptoms as early as possible.

Multiple pregnancy

Definition

A multiple **pregnancy** is a pregnancy in which more than one fetus develops in the uterus at the same time.

Demographics

Multiple pregnancies occur in 1–2% of all pregnancies. The rate of twinning (the bearing of twins) is believed to be underestimated, as twin pregnancies with a singleton birth (an offspring born singly) are usually not recorded as twins.

Multiple births are more likely to occur in women who become pregnant after the age of 35. This is because hormonal changes in the body that occur as the woman ages increase the chance of more than one egg to being released at a time. Treatment for **infertility** also increases the chance of having a multiple pregnancy.

According to the United States Centers for Disease Control and Prevention (CDC) in 2006 there were 137,085 sets of twins born in the United States, 6,118 sets of triplets, 355 sets of quadruplets, and 67 instances of quintuplets or higher order births. That is a rate in twins of 32.1 per 1,000 live births and a rate in triplets or higher order births of 153.3 per 100,000 live births.

Description

A multiple pregnancy may be the result of the natural process of twinning, or it may be the result of the woman having taken fertility drugs. Because of the increase in artificial reproductive technology (ART), the incidence of multiple pregnancies has increased. The CDC reports that since 1980 the number of twins has risen by 52% and the number of triplets and high order multiples (more than three) has increased by 404%. An older maternal age and the use of fertility techniques are seen as the two major factors in these increases. While singletons have a 10% risk of being

WWW.BOOKBAZ.IR

A 3D ultrasound image of twin fetuses. *(© Medical-on-Line/Alamy.)*

born preterm, multiple births have a 57% chance of being born prematurely. Premature birth places a newborn at higher risk for morbidity and mortality.

There are two categories of twins: monozygotic (identical twins) and dizygotic (fraternal twins). Monozygotic twins are twins that have developed from a single fertilized ovum (egg) that splits during embryonic development. These twins have the same genetic makeup and are always the same sex. They may be surrounded by one chorion (the outer embryonic membrane of the developing fetus) or may each have their own chorion. They may be surrounded by one amniotic sac (innermost of the membranes surrounding the embryo) or may each have their own amniotic sac. They may share a placenta or may each have their own placenta. These different possibilities depend on the time of the embryonic development at which the division took place. About 2–5% of monozygotic twins will share one amniotic sac. This rare occurrence puts the twins at risk for umbilical cord entanglement, cessation of blood flow, and death. Double survival of monoamniotic twins is rare.

Dizygotic twins develop from two fertilized ova. Their genetic makeup is different, and they are no more similar as any two siblings in a family. They may be the same or different sex. Each has its own chorion, amniotic sac, and placenta. While each twin has its own placenta, the placental implantations may be close enough that they fuse into one.

Multiple pregnancies of three or more fetuses may be the result of a single fertilized egg that splits, of multiple egg fertilizations, or a combination of the two processes.

Twins may not grow at the same rate. A 25% or more disparity in their growth is referred to as discordance, which occurs in about 10% of twin pregnancies. An extreme case of discordance occurs in the condition called twin-to-twin **transfusion**, also known as twin oligohydramnios-polyhydramnios sequence.

In this situation, one twin becomes the donor twin (receives too little blood from vessels in the fetuses' shared placenta that connect their blood circulations) and the other twin is the recipient (receives too much blood). The donor twin becomes small, pale, hypotensive, and anemic, with very little amniotic fluid. The recipient twin is large, polycythemic, hypertensive, with an excess of amniotic fluid. Both are at risk for **heart failure** and death.

Causes and symptoms

In a woman's menstrual cycle, one egg, or ovum, is normally released every month. If more than one egg is released, it is possible for each egg to be fertilized separately by different sperm cells. Fertility drugs encourage the release of more than one egg during the monthly menstrual cycle. In the case of monozygotic twins, only one egg was released and fertilized; but after fertilization it split, and separate fetuses developed. If the split is not complete, conjoined twins develop. Conjoined twins share certain body parts and organs. They may be referred to as Siamese twins. The chance of multiple pregnancy increases with an increase in maternal age. Genetics and racial background also play a role.

Diagnosis

A multiple pregnancy is suspected if the woman's uterus is growing too quickly for the gestational age, with excessive maternal weight gain, elevated levels of alpha-fetoprotein (a fetal protein that increases in the mother's blood during pregnancy) levels, unexplained severe maternal anemia, or with the auscultation (listening to sound to aid in diagnosis and treatment) of more than one fetal heartbeat. If undiagnosed at the time of quickening, the mother may feel movement in different parts of the uterus at the same time. **Ultrasound** can confirm the presence of a multiple pregnancy. Once the multiple pregnancy is confirmed, ultrasonography may be used to check fetal growth over time, and the presence of any anomalies.

While a mother carrying a singleton may have one ultrasound done during the pregnancy, the mother of a multiple pregnancy is much more likely to have several ultrasounds done. The experience, skill, and ability of the ultrasound technician to provide a calm environment can be a great help to the mother and her partner. The nurse working in a high-risk obstetric practice can provide a great deal of teaching both to inform the mother about what to expect and to decrease **anxiety** through knowledge.

LOUIS GERALD KEITH (1935–)

Louis Gerald Keith and his twin brother, Donald, were born on April 24, 1935, to Russian immigrants. Although the boys received much attention due to their status as twins, their parents encouraged them to pursue their own goals, and at age twelve, Louis decided he wanted to become a doctor. After completing his bachelor of science degree at the University of Illinois, Keith entered the Chicago Medical school, graduating with his degree in 1960. He joined the U.S. Public Health Service and was stationed in Puerto Rico after completing his residency and internship at Cook County Hospital. Keith returned to Chicago after receiving his certification in obstetrics and gynecology in 1967 and worked as a professor and a physician.

Keith began his research on twins when a friend's twin brother died of lymphoma. The fact that Keith was a twin made his research more personally fulfilling and worthwhile to him. Keith and Donald founded the Center for the Study of Multiple Birth in 1977 located in Chicago. The center, a non profit facility, was the first multiple birth research organization in the United States. Keith has delivered many speeches and has published various study results. In addition to books and scientific articles written individually and cooperatively, he was co-author of *Multiple Pregnancy: Epidemiology, Gestation and Prenatal Outcome* (1996) with his brother Donald, and others. He was previously the chief obstetrician at the Prentice Women's Hospital and Maternity Center in Chicago and subsequently professor of obstetrics and gynecology and director of the Section of Undergraduate Education and Medical Student Affairs at Northwestern University Medical School in Chicago.

A condition referred to as vanishing twin syndrome occurs in up to 50% of twin pregnancies diagnosed very early by ultrasound. This syndrome occurs when a twin pregnancy was diagnosed, but later one twin is found to have disappeared. It is not clear what causes this syndrome. In these cases, there may have been early pregnancy vaginal bleeding and a lower human chorionic gonadotropin (hCG; a type of hormone) level than would be expected. The placenta often shows a whitish area and the remnant of a gestational sac. The mother and surviving twin (born singly) are generally both healthy.

Treatment

The diagnosis of a multiple pregnancy will result in it being treated as a **high-risk pregnancy** because of associated maternal and fetal risks. In a triplet pregnancy the mother may be offered the choice of selective

WWW.BOOKBAZ.IR

reduction to twins. However, the literature is unclear as to the overall value of reduction from three to two fetuses. In high order multiples, to decrease the risk of very early preterm birth and potential loss of fetal viability, selective reduction may take place. In selective reduction, high order multiples are reduced to triplets or twins. The procedure is usually completed before the end of the third month of gestation and involves a chemical injection into one or more developing embryos. A fetus that shows chromosomal damage is usually targeted first. While this process increases the chances of the viability of the remaining fetuses, it carries a significant emotional burden for the parents. It also raises ethical issues concerning the "right-to-life" of a fetus. Efforts are being made in the field of ART to prevent the development of high order multiples in order to avoid this situation as much as possible.

KEY TERMS

Chorion—The outer embryonic membrane of the developing fetus that gives rise to the placenta. Inside the chorion is the amniotic sac or sacs, inside of which are the fetuses.

Morbidity—An illness or disease condition. In statistics it refers to the rate at which a disease occurs.

Mortality—Death. In statistics it refers to the rate at which death occurs in a population for a particular disease condition.

Singleton—A fetus that develops alone in the uterus.

Prognosis

Prognosis for a multiple pregnancy depends on many factors. The higher the number of fetuses, the greater the risks. A twin pregnancy carries significantly more risks than a singleton pregnancy. The risks for triplets are similar to that of twins. The risks increase significantly with multiples of four or higher. Twins have a ten-fold risk of perinatal mortality over singletons.

While many multiple pregnancies have an excellent outcome, multiple pregnancy is still considered a high-risk pregnancy. The average gestation for a singleton is 38 to 42 weeks. For twins gestation averages 37 weeks; for triplets, 33 weeks; and for quadruplets, 31 weeks. The mother carrying a multiple pregnancy has an increased risk of:

- premature birth
- pregnancy-related hypertension and preeclampsia
- hydramnios (excess amniotic fluid)
- placenta previa (placenta covering the mouth of the womb-cervix)
- folic acid and iron deficiency
- gestational diabetes
- urinary tract infection
- placental abruption after the vaginal delivery of the first twin (separation of the placenta from the uterus before the baby is born)
- uterine atony (failure of the uterus to contract after birth) and postpartal hemorrhage due to exaggerated stretching of the uterus
- fatigue and backache
- cesarean delivery

The risks to fetuses in a multiple pregnancy are greater than that for a singleton and include:

- premature birth (Preterm labor for twins is seven to ten times more likely than for singletons and is a significant factor in perinatal morbidity and mortality.)
- intrauterine growth restriction
- congenital anomalies
- cerebral palsy with increased risk often due to preterm delivery
- discordance; more common with triplets than with twins
- dead fetus syndrome
- combined pregnancy, in which one twin develops in the uterus while the other is ectopic (other than in the uterus, such as the fallopian tube or peritoneal cavity)
- delayed delivery of second twin
- placental abruption

Prevention

Twinning is a naturally occurring phenomenon and cannot be completely prevented. It occurs more often in older mothers. Multiple births due to ART are a concern because a multiple pregnancy represents a complication of pregnancy. Efforts within the ART community are being made to minimize the incidence of high order multiples. Efforts to prevent or minimize maternal and fetal complications will result in closer monitoring. More frequent ultrasounds, biophysical profile, and/or nonstress tests may be ordered. Cervical length and change may be monitored as an

indicator of preterm delivery. If both twins are vertex and vaginal delivery is attempted, both fetal heart rates will be monitored. Cesarean deliveries of twins are more common than for singletons. This is especially true in high order multiples. The overall cesarean delivery rate tends to be about 75%.

Multiple sclerosis

Definition

Multiple sclerosis (MS) is a chronic autoimmune disorder affecting movement, sensation, and bodily functions. It is caused by destruction of the myelin insulation covering nerve fibers (neurons) in the central nervous system (brain and spinal cord).

Demographics

In 2008, multiple sclerosis affected about 400,000 people in the United States, with 10,000 new cases being diagnosed each year. Worldwide, MS affects between 1.5 and 2.5 million people. Most people have their first symptoms between the ages of 20 and 40; symptoms rarely begin before age 15 or after age 60. Women are almost twice as likely to get MS as men, especially in their early years. People of northern European ancestry are more likely to be affected than people of other racial backgrounds, and MS rates are higher in the United States, Canada, and Northern Europe than other parts of the world. The disorder is unknown among certain native peoples such as the Inuit (native people of the Arctic) and Maori (Native people of New Zealand).

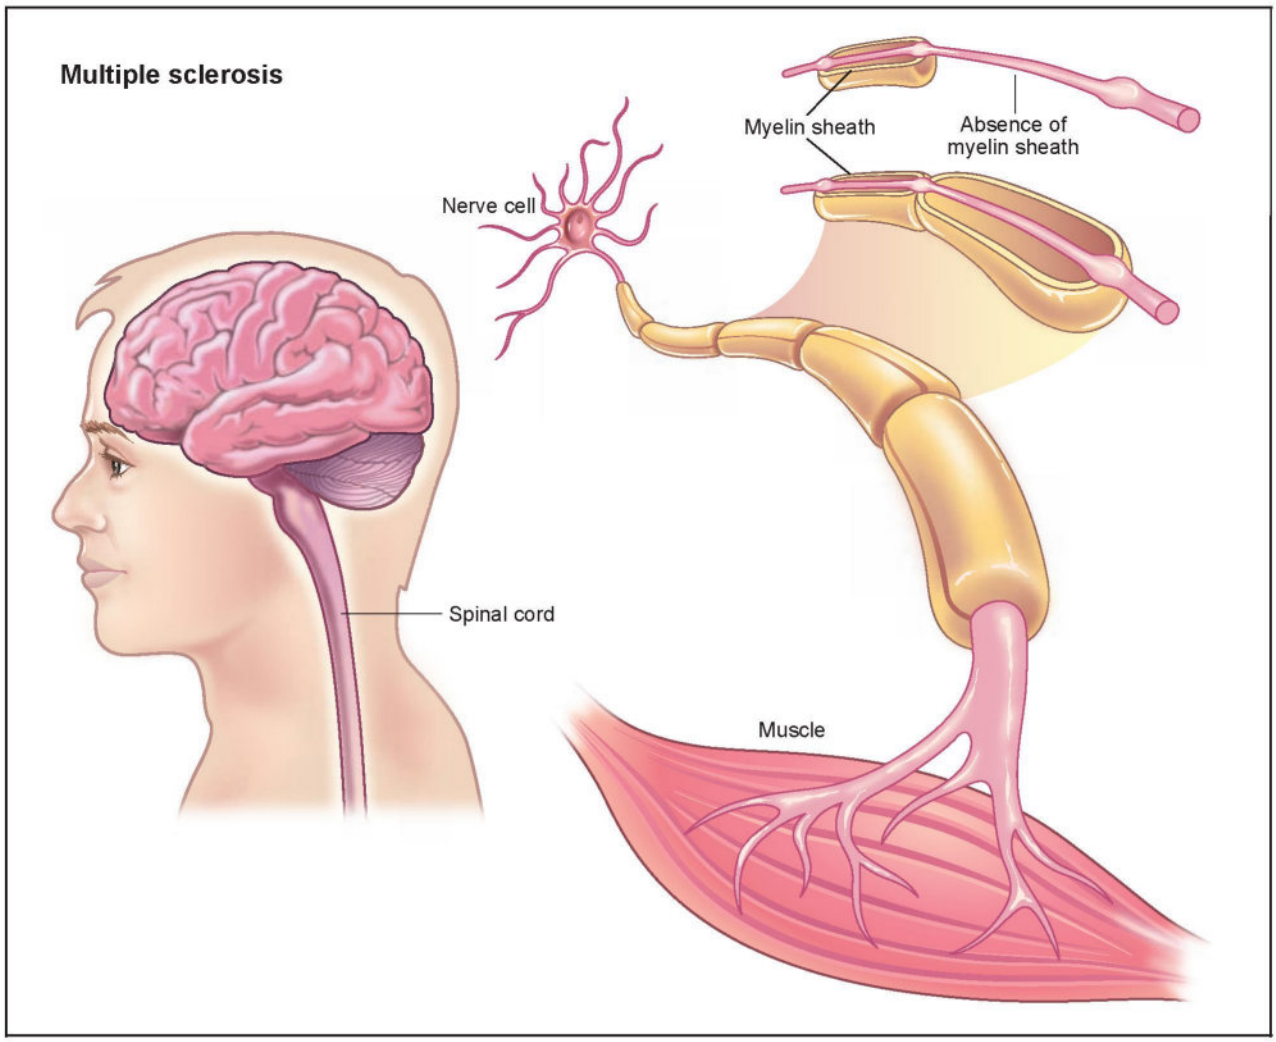
Description

Multiple sclerosis is a slowly progressive disease of the central nervous system (CNS), which is composed of the brain and spinal cord. In 1868, French physician Jean-Martin Charcot (1825-1893) provided the first detailed clinical description of the disease. Today researchers know that MS is an autoimmune disorder that causes the destruction of myelin, the insulating material that surrounds nerve fibers (neurons). Myelin helps electrical signals pass quickly and smoothly between the brain and the rest of the body. When the myelin layer is destroyed, nerve messages are sent more slowly and less efficiently. Patches of scar tissue, called plaques, form over the affected areas, further disrupting nerve communication. The symptoms of MS occur when the brain and spinal cord nerves no longer communicate properly with other parts of the body. MS causes a wide variety of symptoms and can affect vision, balance, strength, sensation, coordination, and bodily functions.

Risk factors

The risk of developing MS is slightly higher if another family member is affected, suggesting the influence of genetic factors. If one person in a family has MS, then that person's close family relatives (parents, children, siblings) have about a 5% greater chance of developing MS than people who do not have family members with the disorder. In addition, the higher prevalence of MS among people of northern European background suggests some genetic susceptibility.

WWW.BOOKBAZ.IR



Multiple sclerosis (MS) is an autoimmune disease in which immune cells attack and destroy the myelin sheath, which stimulates neurons in the brain and spinal cord. When the myelin is destroyed, nerve messages are sent more slowly and less efficiently. Scar tissue then forms over the affected areas, disrupting nerve communication. MS symptoms occur when the brain and spinal cord nerves cease to communicate properly with other parts of the body. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Causes and symptoms

Causes

Multiple sclerosis is an autoimmune disorder, meaning it is caused by the body's own immune system. For unknown reasons, immune cells attack and destroy the myelin sheath that insulates neurons in the brain and spinal cord. This myelin sheath speeds transmission of nerve impulses and prevents electrical activity in one cell from short-circuiting to another cell. Disruption of communication between the brain and other parts of the body prevents normal passage of sensations and control messages, leading to the symptoms of MS. The demyelinated areas appear as plaques, small round areas of gray neuron without the white myelin covering. The progression of symptoms in MS is correlated with development of new plaques in the portion of the brain or spinal cord controlling the affected areas. Because there appears to be no pattern in the appearance of new plaques, the progression of MS can be unpredictable.

Despite considerable research, the trigger for this autoimmune destruction is still unknown. At various times, evidence has pointed to genes, environmental factors, viruses, or a combination of these.

The fact that the risk of developing MS is slightly higher if another family member is affected, suggests that there is a genetic susceptibility to the disease.

The role of an environmental factor is suggested by studies of the effect of migration on the risk of developing MS. Age plays an important role in determining this change in risk—young people in low-risk groups who move into countries with higher MS rates display the risk rates of their new surroundings, while older migrants retain the risk rate of their original home country. One interpretation of these studies is that an environmental factor, either protective or harmful, is acquired in early life; the risk of disorder later in life reflects the effects of the early environment.

These same data can be used to support the involvement of a slow-acting virus, one that is acquired early in live but begins its destructive effects much later. Slow viruses are known to cause other disorders, including **AIDS**. In addition, viruses have been implicated in other **autoimmune disorders**. Many claims have been made for the role of viruses, slow or otherwise, as the trigger for MS, but as of 2014 no strong candidate had emerged.

How a virus could trigger the autoimmune reaction is also unclear. There are two main models of virally induced autoimmunity. The first suggests the immune system is actually attacking a virus (one too well-hidden for detection in the laboratory), and the myelin damage is an unintentional consequence of fighting the infection. The second model suggests the immune system mistakes myelin for a viral protein, one it encountered during a prior infection. Primed for the attack, it destroys myelin because it resembles the previously recognized viral invader.

Either of these models allows a role for genetic factors, since certain genes can increase the likelihood of autoimmunity, and it seems likely that more than one gene is involved in a person's susceptibility to MS. Environmental factors as well might change the sensitivity of the immune system or interact with myelin to provide the trigger for the secondary immune response. Possible environmental triggers that have been invoked in MS include viral infection, **trauma**, electrical injury, and chemical exposure, although controlled studies do not support a causative role.

Symptoms

MS is a diverse disease. No two affected persons are the same and each will experience different combinations of symptoms with differing severity. The symptoms of multiple sclerosis may occur in one of three patterns:

- The most common pattern is the relapsing-remitting pattern, in which there are clearly defined symptomatic attacks lasting 24 hours or more, followed by complete or almost complete improvement. The period between attacks may be a year or more at the beginning of the disorder, but may shrink to several months later on. About three-quarters of all people diagnosed with MS have this version of the disorder. This pattern is especially common in younger people who develop MS.
- In the primary progressive pattern, the disorder progresses without remission or with only occasional plateaus or slight improvements. This pattern is more common in older people. About 10% of people with the disorder have this pattern.
- In the secondary progressive pattern, the person with MS begins with relapses and remissions, followed by more steady progression of symptoms. In some people, what begins as a relapsing-remitting pattern develops into a secondary progressive pattern.

Between 10–20% of people have a benign type of MS, meaning their symptoms progress very little over the course of their lives.

Because plaques may form in any part of the central nervous system, the symptoms of MS vary widely from person-to-person and from stage-to-stage of the disorder. Initial symptoms often include:

- muscle weakness, causing difficulty walking
- loss of coordination or balance
- numbness, "pins and needles," (paresthesias), or other abnormal sensations
- visual disturbances, including blurred or double vision

Later symptoms may include:

- fatigue
- muscle spasticity and stiffness
- tremors
- paralysis
- pain
- vertigo
- speech or swallowing difficulty
- loss of bowel and bladder control
- incontinence, constipation
- sexual dysfunction
- cognitive changes

Weakness in one or both legs is common, and may be the first symptom noticed by a person with MS. Muscle spasticity, where muscles are excessive and continuously contracted, is also common and may be more disabling than weakness.

Double vision or eye tremor (**nystagmus**) may result from involvement of the nerve pathways controlling

WWW.BOOKBAZ.IR

KEY TERMS

Clinical trial—Carefully conducted tests in which effectiveness and side effects are studied, with the placebo effect eliminated.

Evoked potentials—Tests that measure the brain's electrical response to stimulation of sensory organs (eyes or ears) or peripheral nerves (skin). These tests may help confirm the diagnosis of multiple sclerosis.

Myelin—A layer of insulation that surrounds the nerve fibers in the brain and spinal cord.

Plaque—Patches of scar tissue that form where the layer of myelin covering the nerve fibers is destroyed by the multiple sclerosis disorder process.

Primary progressive—A pattern of symptoms of multiple sclerosis in which the disorder progresses without remission or with occasional plateaus or slight improvements.

Relapsing-remitting—A pattern of symptoms of multiple sclerosis in which symptomatic attacks occur that last 24 hours or more, followed by complete or almost complete improvement.

Secondary progressive—A pattern of symptoms of multiple sclerosis in which there are relapses and remissions, followed by more steady progression of symptoms.

movement of the eye muscles. Visual disturbances result from involvement of the optic nerves (**optic neuritis**) and may include development of blind spots in one or both eyes, changes in color vision, or blindness. Optic neuritis usually involves only one eye at a time and is often associated with movement of the effected eye.

More than half of all people affected by MS have **pain** during the course of their disorder, and many experience chronic pain, including pain from spasticity. Acute pain occurs in about 10% of cases. This pain may be a sharp, stabbing pain especially in the face, neck, or down the back. Facial numbness and weakness are also common.

Cognitive changes, including memory disturbances, depression, and personality changes, are found in people affected by MS, although it is not entirely clear whether these changes are due primarily to the disorder or to the psychological reaction to it. Depression may be severe enough to require treatment in up to 25% of those with MS. A smaller number of people experience disorder-related euphoria, or abnormally elevated mood, usually after a long disorder duration and in combination with other psychological changes.

Symptoms of MS may be worsened by heat or increased body temperature, including **fever**, intense physical activity, or exposure to sun, hot baths, or showers.

Diagnosis

There is no single test that confirms the diagnosis of multiple sclerosis, and there are a number of other disorders with similar symptoms. While one person's diagnosis may be immediately suggested by symptoms and history, another's may not be confirmed without multiple tests and prolonged observation. The distribution of symptoms is important: MS affects multiple areas of the body over time. The pattern of symptoms is also critical, especially as evidence of the relapsing-remitting pattern, so a detailed medical history is one of the most important parts of the diagnostic process. A thorough search to exclude other causes of a patient's symptoms is especially important if the following features are present: 1) family history of neurologic disorder, 2) symptoms and findings attributable to a single anatomic location, 3) persistent back pain, 4) age of onset over 60 or under 15 years of age, or 5) progressively worsening disorder.

Tests

In addition to the medical history and a standard **neurological exam**, several lab tests are used to help confirm or rule out a diagnosis of MS:

- Magnetic resonance imaging (MRI) can reveal plaques on the brain and spinal cord. Gadolinium enhancement can distinguish between old and new plaques, allowing a correlation of new plaques with new symptoms. Plaques may be seen in several other disorders as well, including encephalomyelitis, neurosarcoidosis, and cerebral lupus. Plaques on MRI may be difficult to distinguish from small strokes, areas of decreased blood flow, or changes seen with trauma or normal aging.
- A lumbar puncture, or spinal tap, is done to measure levels of immune system proteins, which are usually elevated in the cerebrospinal fluid of a person with MS. This test may not be necessary if other tests are diagnostic.
- Evoked potential tests are electrical tests of conduction speed in the nerves that can reveal reduced speeds consistent with the damage caused by plaques. These tests may be done with small electrical charges applied to the skin (somatosensory evoked

potential), with light patterns flashed on the eyes (visual evoked potential), or with sounds presented to the ears (auditory evoked potential).

The clinician making the diagnosis, usually a neurologist, may classify the disorder as "definite MS," meaning the symptoms and test results all point toward MS as the cause. "Probable MS" and "possible MS" reflect less certainty and may require more time to pass to observe the progression of the disorder and the distribution of symptoms.

Treatment

As of 2014, there was no cure for MS. Nevertheless, several drugs may slow progression of the disorder and moderate some symptoms in many patients, especially if started early.

MS causes a wide variety of symptoms, and the treatments for these are equally diverse. Most symptoms can be treated and complications avoided with good care and attention from medical professionals. Good health and **nutrition** remain important preventive measures. **Vaccination** against **influenza** can prevent respiratory complications. Preventing complications such as **pneumonia**, **bedsores**, injuries from falls, or urinary infection requires attention to the primary problems that may cause them. Shortened life spans with MS are almost always due to complications rather than primary symptoms themselves.

Drugs

Drug treatment of MS must be individualized. Not all drugs are appropriate for all patients. In the United States as of 2014, MS was most often treated with four drugs known as the ABCR drugs. These drugs are interferon beta-1a (Avonex), interferon beta-1b (Betaseron and Rebif) and glatiramer acetate (Copaxone). These drugs, on average, reduce relapses in the relapsing-remitting form of MS by about one-third. Different measurements from tests of each have demonstrated other benefits as well: Avonex may slow the progress of physical impairment, Betaseron and Rebif may reduce the severity of symptoms, and Copaxone may decrease disability. All four drugs are administered by injection, some into muscle (IM), and some under the skin (SC). Some controversy exists on the most effective dose and the frequency with which these drugs should be administered.

Although the ABCR drugs reduce relapses and may keep patients in relatively good health for the short-term, their long-term success has not been proven and they do not work well for patients who have reached a steadily progressive stage of MS. Individuals with progressive forms of MS may be treated with mitoxantrone (Novantrone), cyclophosphamide (Cytoxan, Neosar), azathioprine (Imuran), or methotrexate (Rheumatrex). All these drugs suppress the immune system. None is ideal, and all have potentially serious side effects. Corticosteroid drugs such as methylprednisolone (Medrol) also may be used to reduce inflammation. Long-term use of **corticosteroids** also causes serious side effects.

Training in bowel and bladder care may be needed to prevent or compensate for incontinence. If the urge to urinate becomes great before the bladder is full, some drugs may be helpful, including propantheline bromide (Probanthine), oxybutynin chloride (Ditropan), or imipramine (Tofranil). Baclofen (Lioresal) may relax the sphincter muscle, allowing complete emptying. Intermittent catheterization is effective in controlling bladder dysfunction. In this technique, a catheter is used to periodically empty the bladder.

Spasticity can be treated with oral medications, including baclofen and diazepam (Valium), or by injection with botulinum toxin (Botox). Spasticity relief may also bring relief from chronic pain. More acute types of pain may respond to carbamazepine (Tegretol) or diphenylhydantoin (Dilantin). **Low back pain** is common from increased use of the back muscles to compensate for weakened legs. **Physical therapy** and over-the-counter pain relievers may help.

Fatigue may be partially avoidable with changes in the daily routine to allow more frequent rests. Amantadine (Symmetrel) and Modafinil (Provigil), although not specifically approved for use with MS, are often used to treat fatigue and improve alertness. Pemoline (Cylert), a drug formerly used to treat fatigue in MS patients, was withdrawn from sale in the United States in October 2005 because of potentially fatal liver complications. Visual disturbances often respond to corticosteroids. Other symptoms that may be treated with drugs include seizures, vertigo, and tremor.

Clinical trials of new drugs and drug combinations to treat MS are ongoing. Individuals with MS who wish to participate in the trial of an experimental therapy can find a list of clinical trials currently enrolling volunteers at http://clinicaltrials.gov. There is no cost to the patient to participate in a clinical trial.

Rehabilitative therapy

Physical therapy helps the person with MS to strengthen and retrain affected muscles, maintain range of motion, prevent muscle stiffening, learn to

WWW.BOOKBAZ.IR

use assistive devices such as canes and walkers, and to learn safer and more energy-efficient ways of moving, sitting, and transferring. **Exercise** and stretching programs are usually designed by the physical therapist and taught to the patient and caregivers for use at home. Exercise is an important part of maintaining function for the person with MS. Swimming is often recommended, not only for its low-impact workout, but also because it allows strenuous activity without overheating.

Occupational therapy helps the person with MS adapt to her environment and adapt the environment to her. The occupational therapist suggests alternate strategies and assistive devices for activities of daily living, such as dressing, feeding, and washing, and evaluates the home and work environment for safety and efficiency improvements that may be made.

Alternatives

Bee venom has been suggested as a treatment for MS, but no studies or objective reports support this claim.

In several studies, **marijuana** has been shown to have variable effects on the symptoms of MS. Improvements have been documented for tremor, pain, and spasticity, and worsening for posture and balance. Side effects have included weakness, **dizziness**, relaxation, and incoordination, as well as euphoria.

Some studies support the value of high doses of **vitamins**, **minerals**, and other dietary supplements for controlling disorder progression or improving symptoms. Alpha-linoleic and linoleic acids, as well as selenium and **vitamin E**, have shown effectiveness in the treatment of MS. Selenium and vitamin E act as **antioxidants**. In addition, a diet low in saturated fats, maintained over a long period, may retard the disorder process.

Studies have also shown that t'ai chi can be an effective therapy for MS because it works to improve balance and increase strength.

There are conflicting views about the herb **Echinacea** and its benefit to MS. Some alternative practitioners recommend Echinacea for people with MS. However, Echinacea appears to stimulate different parts of the immune system, particularly immune cells known as macrophages. In MS these cells are very active already and further stimulation could worsen the disorder.

Prognosis

It is difficult to predict how multiple sclerosis will progress in any one person. Most people with MS will be able to continue to walk and function at their work for many years after their diagnosis. The factors associated with the mildest course of MS are being female, having the relapsing-remitting form, having the first symptoms at a younger age, having longer periods of remission between relapses, and initial symptoms of decreased sensation or vision rather than of weakness or incoordination.

Fewer than 5% of people with MS have a severe progressive form, leading to death from complications within five years. At the other extreme, 10–20% have a benign form, with a very slow or no progression of their symptoms. Studies have shown that about seven out of 10 people with MS are still alive 25 years after their diagnosis, compared to about nine out of 10 people of similar age without disorder. On average, MS shortens the lives of affected women by about six years, and men by 11 years. **Suicide** is a significant cause of death in MS, especially in younger patients. Suicide is completed 7.5 times more often in patients with MS than in those without the disorder.

The degree of disability a person experiences five years after onset is, on average, about three-quarters of the expected disability at 10–15 years. A benign course for the first five years usually indicates the disorder will not cause marked disability.

Prevention

There is no known way to prevent multiple sclerosis. Until the cause of the disorder is discovered, this is unlikely to change. Good nutrition, adequate rest, avoidance of **stress**, heat, and extreme physical exertion, and good bladder hygiene may improve quality of life and reduce symptoms.

Mumps

Definition

Mumps is a relatively mild short-term viral infection of the salivary glands that usually occurs during childhood. Typically, mumps is characterized by a painful swelling of both cheek areas, although the person could have swelling on one side or no perceivable swelling at all. The salivary glands are also called the parotid glands, therefore, mumps is sometimes referred to as an inflammation of the parotid glands (epidemic parotitis). The word *mumps* comes from an old English dialect, meaning lumps or bumps within the cheeks.

Description

Mumps is a very contagious infection that spreads easily in such highly populated areas as day care centers and schools. Although not as contagious as **measles** or **chickenpox**, mumps was once quite common. Prior to the release of a mumps vaccine in the United States in 1967, approximately 92% of all children had been exposed to mumps by the age of 15. In these pre-vaccine years, most children contracted mumps between the ages of four and seven. Mumps epidemics came in two to five year cycles. The greatest mumps epidemic was in 1941 when approximately 250 cases were reported for every 100,000 people. In 1968, the year after the live mumps vaccine was released, only 76 cases were reported for every 100,000 people. By 1985, less than 3,000 cases of mumps were reported throughout the entire United States, which works out to about 1 case per 100,000 people. The reason for the decline in mumps was the increased usage of the mumps vaccine. However, 1987 noted a five-fold increase in the incidence of the disease because of the reluctance of some states to adopt comprehensive school immunization laws. Since then, state-enforced school entry requirements have achieved student immunization rates of nearly 100% in kindergarten and first grade. In 1996, the Centers for Disease Control and Prevention (CDC) reported only 751 cases of mumps nationwide, or, in other words, about one case for every five million people.

A young child with mumps. *(SPL/Photo Researchers, Inc.)*

Causes and symptoms

The paramyxovirus that causes mumps is harbored in the saliva and is spread by sneezing, coughing, and other direct contact with another person's infected saliva. Once the person is exposed to the virus, symptoms generally occur in 14-24 days. Initial symptoms include chills, **headache**, loss of appetite, and a lack of energy. However, an infected person may not experience these initial symptoms. Swelling of the salivary glands in the face (parotitis) generally occurs within 12–24 hours of the above symptoms. Accompanying the **swollen glands** is **pain** on chewing or swallowing, especially with acidic beverages, such as lemonade. A **fever** as high as 104°F (40°C) is also common. Swelling of the glands reaches a maximum on about the second day and usually disappears by the seventh day. Once a person has contracted mumps, they become immune to the disease, despite how mild or severe their symptoms may have been.

While the majority of cases of mumps are uncomplicated and pass without incident, some complications can occur. Complications are, however, more noticeable in adults who get the infection. In 15% of cases, the covering of the brain and spinal cord becomes inflamed (**meningitis**). Symptoms of meningitis usually develop within four or five days after the first signs of mumps. These symptoms include a stiff neck, headache, **vomiting**, and a lack of energy. Mumps meningitis is usually resolved within seven days, and damage to the brain is exceedingly rare.

The mumps infection can spread into the brain causing inflammation of the brain (encephalitis).

WWW.BOOKBAZ.IR

Symptoms of mumps encephalitis include the inability to feel pain, seizures, and high fever. Encephalitis can occur during the parotitis stage or one to two weeks later. Recovery from mumps encephalitis is usually complete, although complications, such as seizure disorders, have been noted. Only about 1 in 100 with mumps encephalitis dies from the complication.

About one-quarter of all post-pubertal males who contract mumps can develop a swelling of the scrotum (**orchitis**) about seven days after the parotitis stage. Symptoms include marked swelling of one or both testicles, severe pain, fever, nausea, and headache. Pain and swelling usually subside after five to seven days, although the testicles can remain tender for weeks.

Girls occasionally suffer an inflammation of the ovaries, or oophoritis, as a complication of mumps, but this condition is far less painful than orchitis in boys.

As of late 2002, some researchers in Europe were studying the possibility that mumps increases a person's risk of developing inflammatory bowel disease (IBD) in later life. This hypothesis required further research, as present findings are inconclusive.

Diagnosis

When mumps reaches epidemic proportions, diagnosis is relatively easy on the basis of the physical symptoms. The doctor will take the child's temperature, gently palpate (touch) the skin over the parotid glands, and look inside the child's mouth. If the child has mumps, the openings to the ducts inside the mouth will be slightly inflamed and have a "pouty" appearance. With so many people vaccinated today, a case of mumps must be properly diagnosed in the event the salivary glands are swollen for reasons other than viral infection. For example, in persons with poor **oral hygiene**, the salivary glands can be infected with bacteria. In these cases, **antibiotics** are necessary. Also in rare cases, the salivary glands can become blocked, develop tumors, or swell due to the use of certain drugs, such as iodine. A test can be performed to determine whether the person with swelling of the salivary glands actually has the mumps virus.

As of late 2002, researchers in London reported the development of a bioassay for measuring mumps-specific IgG. This test would allow a doctor to check whether an individual patient is immune to mumps, and allow researchers to measure the susceptibility of a local population to mumps in areas with low rates of **vaccination**.

Treatment

When mumps does occurs, the illness is usually allowed to run its course. The symptoms, however, are treatable. Because of difficulty swallowing, the most important challenge is to keep the patient fed and hydrated. The individual should be provided a soft diet, consisting of cooked cereals, mashed potatoes, broth-based soups, prepared baby foods, or foods put through a home food processor. **Aspirin**, **acetaminophen**, or ibuprofen can relieve some of the pain due to swelling, headache, and fever. Avoid fruit juices and other acidic foods or beverages that can irritate the salivary glands. Avoid dairy products that can be hard to digest. In the event of complications, a physician should be contacted at once. For example, if orchitis occurs, a physician should be called. Also, supporting the scrotum in a cotton bed on an adhesive-tape bridge between the thighs can minimize tension. Ice packs are also helpful.

Alternatives

Acupressure can be used effectively to relieve pain caused by swollen glands. The patient can, by using the middle fingers, gently press the area between the jawbone and the ear for two minutes while breathing deeply.

A number of homeopathic remedies can be used for the treatment of mumps. For example, belladonna may be useful for flushing, redness, and swelling. Bryonia (wild hops) may be useful for irritability, lack of energy, or thirst. Phytolacca (poke root) may be prescribed for extremely swollen glands. A homeopathic physician should always be consulted for appropriate doses for children, and remedies that do not work within one day should be stopped. A homeopathic preparation of the mumps virus can also be used prophylactically or as a treatment for the disease.

Several herbal remedies may be useful in helping the body recover from the infection or may help alleviate the discomfort associated with the disease. **Echinacea** (*Echinacea* spp.) can be used to boost the immune system and help the body fight the infection. Other herbs taken internally, such as cleavers (*Galium aparine*), calendula (*Calendula officinalis*), and phytolacca (poke root), target the lymphatic system and may help to enhance the activity of the body's internal filtration system. Since phytolacca can be toxic, it should only be used by patients under the care of a skilled practitioner. Topical applications are also useful in relieving the discomfort of mumps. A cloth dipped in a heated mixture of vinegar and cayenne (*Capsicum frutescens*) can be wrapped around the

KEY TERMS

Asymptomatic—Characteristic of persons who carry a disease and may be capable of transmitting the disease but who do not exhibit symptoms of the disease are said to be asymptomatic.

Autism—A severe developmental disorder that usually begins before three years of age and affects a child's social as well as intellectual development. Some researchers theorized that immunization with the MMR vaccine was a risk factor for autism.

Encephalitis—Inflammation of the brain.

Epidemic parotitis—The medical name for mumps.

Immunoglobulin G (IgG)—A group of antibodies against certain viral infections that circulate in the bloodstream. One type of IgG is specific against the mumps paramyxovirus.

Meningitis—Inflammation of the membranes covering the brain and spinal cord.

Orchitis—Inflammation or swelling of the scrotal sac containing the testicles.

Paramyxovirus—A genus of viruses that includes the causative agent of mumps.

Parotitis—Inflammation and swelling of the salivary glands.

neck several times a day. Cleavers or calendula can also be combined with vinegar, heated, and applied in a similar manner.

Prognosis

When mumps is uncomplicated, prognosis is excellent. However, in rare cases, a relapse occurs after about two weeks. Complications can also delay complete recovery.

Prevention

A vaccine exists to protect against mumps. The vaccine preparation (MMR) is usually given as part of a combination injection that helps protect against measles, mumps, and **rubella**. MMR is a live vaccine administered in one dose between the ages of 12-15 months, 4-6 years, or 11-12 years. Persons who are unsure of their mumps history and/or mumps vaccination history should be vaccinated. Susceptible healthcare workers, especially those who work in hospitals, should be vaccinated. Because mumps is still prevalent throughout the world, susceptible persons over age one who are traveling abroad would benefit from receiving the mumps vaccine.

The mumps vaccine is extremely effective, and virtually everyone should be vaccinated against this disease. There are, however, a few reasons why people should *not* be vaccinated against mumps:

- Pregnant women who contract mumps during pregnancy have an increased rate of miscarriage, but not birth defects. As a result, pregnant women should not receive the mumps vaccine because of the possibility of damage to the fetus. Women who have had the vaccine should postpone pregnancy for three months after vaccination.
- Unvaccinated persons who have been exposed to mumps should not get the vaccine, as it may not provide protection. The person should, however, be vaccinated if no symptoms result from the exposure to mumps.
- Persons with minor fever-producing illnesses, such as an upper respiratory infection, should not get the vaccine until the illness has subsided.
- Because mumps vaccine is produced using eggs, individuals who develop hives, swelling of the mouth or throat, dizziness, or breathing difficulties after eating eggs should not receive the mumps vaccine.
- Persons with immune deficiency diseases and/or those whose immunity has been suppressed with anti-cancer drugs, corticosteroids, or radiation should not receive the vaccine. Family members of immunocompromised people, however, should get vaccinated to reduce the risk of mumps.
- The CDC recommends that all children infected with human immunodeficiency disease (HIV) who are asymptomatic should receive an the MMR vaccine at 15 months of age.

The mumps vaccine has been controversial because of concern that its use was linked to a rise in the rate of childhood **autism**. The negative publicity given to the vaccine in the mass media led some parents to refuse to immunize their children with the MMR vaccine. One result was an increase in the number of mumps outbreaks in several European countries, including Italy and the United Kingdom.

In the fall of 2002, the *New England Journal of Medicine* published a major Danish study disproving

WWW.BOOKBAZ.IR

the hypothesis of a connection between the MMR vaccine and autism. A second study in Finland showed that the vaccine is not associated with aseptic meningitis or encephalitis as well as autism. Since these studies were published, American primary care physicians have once again reminded parents of the importance of immunizing their children against mumps and other childhood diseases.

Munchausen syndrome

Definition

Munchausen syndrome is a psychiatric disorder that causes an individual to self-inflict injury or illness or to fabricate symptoms of physical or mental illness, in order to receive medical care or hospitalization. In a variation of the disorder, Munchausen by proxy (MSBP), an individual, typically a mother, intentionally causes or fabricates illness in a child or other person under her care.

Description

Munchausen syndrome takes its name from Baron Karl Friederich von Munchausen, an eighteenth-century German military man known for his exaggerated stories. The disorder first appeared in psychiatric literature in the early 1950s when it was used to describe patients who sought hospitalization by inventing symptoms and complicated medical histories and/or inducing illness and injury in themselves. Categorized as a factitious disorder (a disorder in which the physical or psychological symptoms are under voluntary control), Munchausen's syndrome seems to be motivated by a need to assume the role of a patient. Unlike **malingering**, there does not seem to be any clear secondary gain (e.g., money) in Munchausen syndrome.

Demographics

Munchausen syndrome most commonly affects people between the ages of 30 and 40. Some studies suggest that more than 3% of patients with a **fever of unknown origin** are actually inducing that **fever** as a component of Munchausen syndrome.

Individuals with Munchausen by proxy syndrome use their child (or another dependent person) to fulfill their need to step into the patient role. About 86% of the time, the parent who is causing these illnesses is the child's mother. About 52% of child victims of Munchausen by proxy are between the ages of three and 13. Parents with MSBP may only exaggerate or fabricate their child's symptoms, or they may deliberately induce symptoms through various methods, including **poisoning**, suffocation, **starvation**, or purposely inoculating their child with an infection. About 9%–31% of children victimized by Munchausen by proxy syndrome die of a related condition elicited by the adult perpetrator.

Causes and symptoms

The exact cause of Munchausen syndrome is unknown. It has been theorized that Munchausen patients are motivated by a desire to be cared for, a need for attention, dependency, an ambivalence toward doctors, or a need to suffer. Factors that may predispose an individual to Munchausen's include a serious illness in childhood or an existing personality disorder.

The Munchausen patient presents a wide array of physical or psychiatric symptoms, usually limited only by their medical knowledge. Many Munchausen patients are familiar with medical terminology and symptoms. Some common complaints include fevers, **rashes**, abscesses, bleeding, and **vomiting**. Common Munchausen by proxy symptoms include apnea (cessation of breathing), fever, vomiting, and **diarrhea**. In both Munchausen and MSBP syndromes, the suspected illness does not respond to a normal course of treatment. Patients or parents may push for invasive diagnostic procedures and display an extraordinary depth of knowledge of medical procedures.

Diagnosis

Because Munchausen sufferers often go from doctor to doctor, gaining admission into many hospitals along the way, diagnosis can be difficult. They are typically detected rather than diagnosed. During a course of treatment, they may be discovered by a hospital employee who encountered them during a previous hospitalization. Their caregivers may also notice that symptoms such as high fever occur only when the patient is left unattended. Occasionally, unprescribed medication used to induce symptoms is found with the patient's belongings. When these patients are confronted, they often react with outrage and check out of the hospital to seek treatment at another facility with a new caregiver.

Treatment

There is no clearly effective treatment for Munchausen syndrome. Extensive **psychotherapy** may be helpful with some Munchausen patients. If Munchausen syndrome coexists with other mental disorders, such as a personality disorder, the underlying disorder is typically treated first.

Prognosis

The infections and injuries Munchausen patients self-inflict can cause serious illness. Patients often undergo countless unnecessary surgeries throughout their lifetimes. In addition, because of their frequent hospitalizations, they have difficulty holding down a job. Further, their chronic health complaints may damage interpersonal relationships with family and friends. Children victimized by sufferers of MSBP are at a real risk for serious injury and possible death. Those who survive physically unscathed may suffer developmental problems later in life.

KEY TERMS

Apnea—A cessation of breathing.

Factitious disorder—A disorder in which the physical or psychological symptoms are under voluntary control.

Prevention

Because the cause of Munchausen syndrome is unknown, formulating a prevention strategy is difficult. Some medical facilities and healthcare practitioners have attempted to limit hospital admissions for Munchausen patients by sharing medical records. While these attempts may curb the number of hospital admissions, they do not treat the underlying disorder and may endanger Munchausen sufferers who have made themselves critically ill and require treatment. Children who are found to be victims of persons with Munchausen by proxy syndrome should be immediately removed from the care of the abusing parent or guardian.

Muscle relaxants

Definition

Skeletal muscle relaxants are drugs that help loosen up or relax the muscles that control skeletal (body) movements. They are a separate class of drugs from the muscle relaxant drugs, given intravenously, to relax the same muscles for surgery or intubation.

Purpose

Skeletal muscle relaxants may be used to relieve spastic or tight muscles in diseases like **tetanus**, **multiple sclerosis**, **spinal cord injury**, or **stroke**. They are also used to relieve **muscle spasms** following injuries or minor muscle strains. Dantrolene (Dantrium) has been used to prevent or treat **malignant hyperthermia** in **anesthesia** or surgery.

Description

Skeletal muscle relaxants are divided into two groups: one, containing most of the drugs in this class, acts via the central nervous system to relax muscles; Dantrium is the only drug that acts directly on muscles.

Baclofen (Lioresal) may be administered orally or injected directly into the spinal-fluid sac to control muscle spasms.

Carisoprodol (Soma), chlorphenesin (Maolate), chlorzoxazone (Paraflex), cyclobenzaprine (Flexeril), diazepam (Valium), metaxalone (Skelaxin), methocarbamol (Robaxin), and orphenadrine (Norflex) are used, along with rest and perhaps **physical therapy**, to treat muscle spasms from sprains and minor injuries and to assist in **rehabilitation** following serious illness, major surgery, or stroke.

Diazepam (Valium) and methocarbamol (Robaxin) can be given by injection to relieve muscle spasms associated with tetanus.

Recommended dosage

Dose varies with the drug, route of administration, and purpose. There may be individual variations in absorption that require doses higher than those usually recommended. Consult specific references for further information.

Precautions

All drugs in this class may cause **sedation**. Baclofen, when injected into the spinal fluid sac, may produce unconsciousness, **shock**, and **respiratory failure**.

Diazepam may be addictive.

Dantrolene may damage the liver.

Tizanidine may cause low blood pressure; this may be controlled by starting with a low dose and increasing the dose gradually. Rarely, it can cause liver damage.

Methocarbamol and chlorzoxazone may cause harmless color changes in urine—orange or reddish-purple with chlorzoxazone and purple, brown, or green with methocarbamol. The urine will return to its normal color when the patient stops taking the medicine.

Not all drugs in this group have been evaluated for safety in **pregnancy** and breast feeding.

Baclofen passes into breast milk; breast feeding while taking it is not recommended.

Diazepam crosses the placenta and into breast milk; breast fed babies may become drowsy and lethargic.

Side effects

Drugs in this class may produce **dizziness**, drowsiness, or headaches. Alcohol may increase these effects.

Paradoxically, these drugs may cause stimulation and irritability.

Skeletal muscle relaxant drugs may cause **rashes**, with or without **itching**.

These drugs may produce upset stomach and nausea.

KEY TERMS

Central nervous system—The brain and spinal cord.

Sedative—Medicine used to treat nervousness or restlessness.

Spasm—Sudden, involuntary tightening or tensing of a muscle or a group of muscles.

Tranquilizer (minor)—A drug that has a calming effect and is used to treat anxiety and emotional tension.

Interactions

Skeletal muscle relaxants have many potential **drug interactions**. Individual references should be consulted.

Because these drugs cause sedation, they should be used with caution with other drugs that may also cause drowsiness.

The activity of diazepam may be increased by drugs that inhibit its metabolism in the liver. These include: Cimetidine, **oral contraceptives**, Disulfiram, Fluoxetine, Isoniazid, Ketoconazole, Metoprolol, Propoxyphene, Propranolol, and Valproic acid.

Dantrolene may have an interaction with estrogens. Although no interaction has been demonstrated, the rate of liver damage in women over the age of 35 who were taking estrogens is higher than in other groups.

Samuel D. Uretsky, PharmD

Muscle spasms and cramps

Definition

Muscle spasms and cramps are spontaneous, often painful muscle contractions.

Description

Most people are familiar with the sudden **pain** of a muscle cramp. The rapid, uncontrolled contraction, or spasm, happens unexpectedly, with either no stimulation or some trivially small one. The muscle contraction and pain last for several minutes and then slowly ease. Cramps may affect any muscle, but are most common in the calves, feet, and hands. While painful, they are harmless, and in most cases, not related to any underlying disorder. Nonetheless, cramps and spasms can be manifestations of many neurological or muscular diseases.

The terms cramp and spasm can be somewhat vague, and they are sometimes used to include types of abnormal muscle activity other than sudden painful contraction. These include stiffness at rest, slow muscle relaxation, and spontaneous contractions of a muscle at rest (fasciculation). Fasciculation is a type of painless muscle spasm, marked by rapid, uncoordinated contraction of many small muscle fibers. A critical part of diagnosis is to distinguish these different meanings and to allow the patient to describe the problem as precisely as possible.

Causes and symptoms

Causes

Normal voluntary muscle contraction begins when electrical signals are sent from the brain through the spinal cord along nerve cells called motor neurons. These include both the upper motor neurons within the brain and the lower motor neurons within the spinal cord and leading out to the muscle. At the muscle, chemicals released by the motor neuron stimulate the internal release of **calcium** ions from stores within the muscle cell. These calcium ions then interact with muscle proteins within the cell, causing the proteins (actin and myosin) to slide past one another. This motion pulls their fixed ends closer, thereby shortening the cell and, ultimately, the muscle itself. Recapture of calcium and unlinking of actin and myosin allows the muscle fiber to relax.

Abnormal contraction may be caused by abnormal activity at any stage in this process. Certain mechanisms within the brain and the rest of the central nervous system help regulate contraction. Interruption of these mechanisms can cause spasm. Motor neurons that are overly sensitive may fire below their normal thresholds. The muscle membrane itself may be overly sensitive, causing contraction without stimulation. Calcium ions may not be recaptured quickly enough, causing prolonged contraction.

Interruption of brain mechanisms and overly sensitive motor neurons may result from damage to the nerve pathways. Possible causes include **stroke**, **multiple sclerosis**, **cerebral palsy**, neurodegenerative diseases, **trauma**, **spinal cord injury**, and nervous system poisons such as strychnine, **tetanus**, and certain

WWW.BOOKBAZ.IR

insecticides. Nerve damage may lead to a prolonged or permanent muscle shortening called contracture.

Changes in muscle responsiveness may be due to or associated with:

- Prolonged exercise. Curiously, relaxation of a muscle actually requires energy to be expended. The energy is used to recapture calcium and to unlink actin and myosin. Normally, sensations of pain and fatigue signal that it is time to rest. Ignoring or overriding those warning signals can lead to such severe energy depletion that the muscle cannot be relaxed, causing a cramp. The familiar advice about not swimming after a heavy meal, when blood flow is directed away from the muscles, is intended to avoid this type of cramp. Rigor mortis, the stiffness of a corpse within the first 24 hours after death, is also due to this phenomenon.
- Dehydration and salt depletion. This may be brought on by protracted vomiting or diarrhea or by copious sweating during prolonged exercise, especially in high temperatures. Loss of fluids and salts—especially sodium, potassium, magnesium, and calcium—can disrupt ion balances in both muscle and nerves. This can prevent them from responding and recovering normally, and can lead to cramp.
- Metabolic disorders that affect the energy supply in muscle. These are inherited diseases in which particular muscle enzymes are deficient. They include deficiencies of myophosphorylase (McArdle's disease), phosphorylase b kinase, phosphofructokinase, phosphoglycerate kinase, and lactate dehydrogenase.
- Myotonia. This causes stiffness due to delayed relaxation of the muscle, but does not cause the spontaneous contraction usually associated with cramps. However, many patients with myotonia do experience cramping from exercise. Symptoms of myotonia are often worse in the cold. Myotonias include myotonic dystrophy, myotonia congenita, paramyotonia congenita, and neuromyotonia.

Fasciculations may be due to **fatigue**, cold, medications, metabolic disorders, nerve damage, or neurodegenerative disease, including **amyotrophic lateral sclerosis**. Most people experience brief, mild fasciculations from time to time, usually in the calves.

Symptoms

The pain of a muscle cramp is intense, localized, and often debilitating Coming on quickly, it may last for minutes and fade gradually. **Contractures** develop more slowly, over days or weeks, and may be permanent if untreated. Fasciculations may occur at rest or after muscle contraction and may last several minutes.

KEY TERMS

Motor neuron—Nerve cells within the central nervous system that carry nerve impulses controlling muscle movement.

Diagnosis

Abnormal contractions are diagnosed through a careful medical history, physical and neurological examination, and **electromyography** of the affected muscles. Electromyography records electrical activity in the muscle during rest and movement.

Treatment

Most cases of simple cramps require no treatment other than patience and stretching. Gently and gradually stretching and massaging the affected muscle may ease the pain and hasten recovery. In some cases **hydrotherapy**, **yoga**, or **massage therapy** may prove beneficial.

More prolonged or regular cramps may be treated with drugs such as carbamazepine, phenytoin, or quinine. Fluid and salt replacement, either orally or intravenously, is used to treat **dehydration**. Treatment of underlying metabolic or neurologic disease, where possible, may help relieve symptoms.

Alternatives

Cramps may be treated or prevented with Gingko (*Ginkgo biloba*) or Japanese quince (*Chaenomeles speciosa*). Supplements of **vitamin E**, niacin, calcium, and magnesium may also help. Taken at bedtime, they may help to reduce the likelihood of night cramps.

Prognosis

Occasional cramps are common and have no special medical significance.

Prevention

The likelihood of developing cramps may be reduced by eating a healthy diet with appropriate levels of **minerals**, and getting regular **exercise** to build up energy reserves in muscle. Avoiding exercising in extreme heat helps prevent heat cramps. Heat cramps can also be avoided by taking salt tablets and water before prolonged exercise in extreme heat. Taking a warm bath before bedtime may increase circulation to the legs and reduce the incidence of nighttime leg cramps.

Muscular dystrophy

Definition

Muscular dystrophy (MD) is the name for a group of inherited disorders in which strength and muscle bulk gradually decline. Nine types of muscular dystrophies are generally recognized.

Demographics

According to National Institute for Neurological Disorders and **Stroke** (NINDS), MD occurs worldwide, and affects all races. Its incidence varies, as some types are more common than others. The most common forms in children are Duchenne and Becker MD and affect approximately 1 in every 3,500 to 5,000 boys, or between 400 and 600 live male births each year in the United States. Between 400 and 600 boys in the United States are born with these conditions each year. Females are rarely affected by these forms of muscular dystrophy. In Europe, the prevalence of Duchenne and Becker MD is 5 per 100,000 individuals.

Description

The muscular dystrophies include:

- Duchenne muscular dystrophy (DMD): DMD affects young boys, causing progressive muscle weakness, usually beginning in the legs. It is a severe form of muscular dystrophy. DMD occurs in about one in 3,500 male births and affects approximately 8,000 boys and young men in the United States. A milder form occurs in a very small number of female carriers.
- Becker muscular dystrophy (BMD): BMD affects older boys and young men, following a milder course than DMD. It occurs in about one in 30,000 male births.
- Emery–Dreifuss muscular dystrophy (EDMD): EDMD affects both males and females because it can be inherited as an autosomal dominant or recessive disorder. Symptoms include contractures and weakness in the calves, weakness in the shoulders and upper arms, and problems in the way electrical impulses travel through the heart to make it beat (heart conduction defects). Fewer than 300 cases of EDMD have been reported in the medical literature.
- Limb–girdle muscular dystrophy (LGMD): LGMD begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles around the hips and shoulders, and weakness in the limbs. It is the most variable of the muscular dystrophies, and there are several different forms of the condition now recognized. Many people with suspected LGMD have probably been misdiagnosed in the past, and therefore, the prevalence of the condition is difficult to estimate. The highest prevalence of LGMD is in a small mountainous Basque province in northern Spain, where the condition affects 69 persons per million.
- Facioscapulohumeral muscular dystrophy (FSH): FSH, also known as Landouzy–Dejerine condition, begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles of the face, shoulders, and upper arms. The hips and legs may also be affected. FSH occurs

WWW.BOOKBAZ.IR

in about one out of every 20,000 people, and affects approximately 13,000 people in the United States.

- Myotonic dystrophy: Also known as Steinert's disease, it affects both men and women, causing generalized weakness first seen in the face, feet, and hands. It is accompanied by the inability to relax the affected muscles (myotonia). Symptoms may begin from birth through adulthood. It is the most common form of muscular dystrophy, affecting more than 30,000 people in the United States.
- Oculopharyngeal muscular dystrophy (OPMD): OPMD affects adults of both sexes, causing weakness in the eye muscles and throat. It is most common among French Canadian families in Quebec, and in Spanish American families in the southwestern United States.
- Distal muscular dystrophy (DD): DD is a group of rare muscle diseases that have weakness and wasting of the distal (farthest from the center) muscles of the forearms, hands, lower legs, and feet in common. In general, the DDs are less severe, progress more slowly, and involve fewer muscles than the other dystrophies. DD usually begins in middle age or later, causing weakness in the muscles of the feet and hands. It is most common in Sweden, and rare in other parts of the world.
- Congenital muscular dystrophy (CMD): CMD is a rare group of muscular dystrophies that have in common the presence of muscle weakness at birth (congenital), and abnormal muscle biopsies. CMD results in generalized weakness, and usually progresses slowly. A subtype, called Fukuyama CMD, also involves intellectual disability (ID) and is more common in Japan.

Risk factors

Since the muscular dystrophies are inherited, people with a family history of MD are at increased risk.

Causes and symptoms

The muscular dystrophies are genetic conditions, meaning they are caused by alterations in genes. Genes, which are linked together on chromosomes, have two functions; they code for the production of proteins, and they are the material of inheritance. Parents pass along genes to their children, providing them with a complete set of instructions for making their own proteins.

Because both parents contribute genetic material to their offspring, each child carries two copies of almost every gene, one from each parent. For some conditions to occur, both copies must be altered. Such conditions are called autosomal recessive conditions. Some forms of LGMD and DD exhibit this pattern of inheritance, as does CMD. A person with only one altered copy, called a carrier, will not have the condition, but may pass the altered gene on to his children. When two carriers have children, the chances of having a child with the condition is one in four for each **pregnancy**.

Other conditions occur when only one altered gene copy is present. Such conditions are called autosomal dominant conditions. DM, FSH, and OPMD exhibit this pattern of inheritance, as do some forms of DD and LGMD. When a person affected by the condition has a child with someone not affected, the chances of having an affected child is one in two.

Because of chromosomal differences between the sexes, some genes are not present in two copies. The chromosomes that determine whether a person is male or female are called the X and Y chromosomes. A person with two X chromosomes is female, while a person with one X and one Y is male. While the X chromosome carries many genes, the Y chromosome carries almost none. Therefore, a male has only one copy of each gene on the X chromosome, and if it is altered, he will have the condition that alteration causes. Such conditions are said to be X-linked. X-linked conditions include DMD, BMD, and EDMD. Women are not usually affected by X-linked conditions, since they will likely have one unaltered copy between the two chromosomes. Some female carriers of DMD have a mild form of the condition, probably because their one unaltered gene copy is shut down in some of their cells.

Women carriers of X-linked conditions have a one in two chance of passing the altered gene on to each child born. Daughters who inherit the altered gene will be carriers. A son born without the altered gene will be free of the condition and cannot pass it on to his children. A son born with the altered gene will have the condition. He will pass the altered gene on to each of his daughters, who will then be carriers, but to none of his sons (because they inherit his Y chromosome).

Not all genetic alterations are inherited. As many as one third of the cases of DMD are due to new mutations that arise during egg formation in the mother. New mutations are less common in other forms of muscular dystrophy.

Several of the muscular dystrophies, including DMD, BMD, CMD, and most forms of LGMD, are due to alterations in the genes for a complex of muscle proteins. This complex spans the muscle cell membrane

(a thin sheath that surrounds each muscle cell) to unite a fibrous network on the interior of the cell with a fibrous network on the outside. Theory holds that by linking these two networks, the complex acts as a "shock absorber," redistributing and evening out the forces generated by contraction of the muscle, thereby preventing rupture of the muscle membrane. Alterations in the proteins of the complex lead to deterioration of the muscle during normal contraction and relaxation cycles. Symptoms of these conditions set in as the muscle gradually exhausts its ability to repair itself.

Both DMD and BMD are caused by alterations in the gene for the protein called dystrophin. The alteration leading to DMD prevents the formation of any dystrophin, while that of BMD allows some protein to be made, accounting for the differences in severity and age of onset between the two conditions. Differences among the other muscular dystrophies in terms of the muscles involved and the ages of onset are less easily explained.

A number of genes have been found to cause LGMD. A majority of the more severe autosomal recessive types of LGMD with childhood–onset are caused by alterations in the genes responsible for making proteins called sarcoglycans. The sarcoglycans are a complex of proteins that are normally located in the muscle cell membrane along with dystrophin. Loss of these proteins causes the muscle cell membrane to lose some of its shock absorber qualities. The genes responsible include LGMD2D on chromosome 17, which codes for the alpha–sarcoglycan protein; LGMD2E on chromosome 4, which codes for the beta–sarcoglycan protein; LGMD2C on chromosome 13, which codes for the gamma–sarcoglycan protein; and LGMD2F on chromosome 5, which codes for the delta–sarcoglycan protein. Some cases of autosomal recessive LGMD are caused by an alteration in a gene, LGMD2A, on chromosome 15, which codes for a muscle enzyme, calpain 3. The relationship between this alteration and the symptoms of the condition is unclear. Alterations in a gene called LGMD2B on chromosome 2 that codes for the dysferlin protein, is also responsible for a minority of autosomal recessive LGMD cases. The exact role of dysferlin is not known. Finally, alterations in the LGMD2G gene on chromosome 17 which codes for a protein, telethonin, is responsible for autosomal recessive LGMD in two reported families. The exact role of telethonin is not known. Some families with autosomal recessive LGMD are not accounted for by alterations in any of the above mentioned genes, indicating that there are as yet undiscovered genes which can cause LGMD. The autosomal dominant LGMD genes have mostly been described in single families. These types of LGMD are considered quite rare.

The genes causing these types of LGMD, their chromosomal location, and the proteins they code for (when known) are listed below:

- LGMD1A (chromosome 5): myotilin
- LGMD1B (chromosome 1): laminin
- LGMD1C (chromosome 3): caveolin
- LGMD1D (chromosome 6)
- LGMD1E (chromosome 7)
- COL6A1 (chromosome 21): collagen VI alpha 1
- COL6A2 (chromosome 21): collagen VI alpha 2
- COL6A3 (chromosome 2): collagen VI alpha 3

The causes of the other muscular dystrophies are not as well understood:

- EDMD is due to a alteration in the gene for a protein called emerin, which is found in the membrane of a cell's nucleus, but whose exact function is unknown.
- Myotonic dystrophy is caused by alterations in a gene on chromosome 19 for an enzyme called myotonin protein kinase that may control the flow of charged particles within muscle cells. This gene alteration is called a triple repeat, meaning it contains extra triplets of DNA code. It is possible that this alteration affects nearby genes as well, and that the widespread symptoms of myotonic dystrophy are due to a range of genetic disruptions.
- The gene for OPMD appears to also be altered with a triple repeat. The function of the affected protein may involve translation of genetic messages in a cell's nucleus.
- The gene(s) for FSH is located on the long arm of chromosome 4 at gene location 4q35. Nearly all cases of FSH are associated with a deletion (missing piece) of genetic material in this region. Researchers are investigating the molecular connection of this deletion and FSH. It is not yet certain whether the deleted material contains an active gene or changes the regulation or activity of a nearby FSH gene. A small number of FSH cases are not linked to chromosome 4. Their linkage to any other chromosome or genetic feature is under investigation.
- The gene(s) responsible for DD have not yet been found.
- About 50% of individuals with CMD have their condition as a result of deficiency in a protein called merosin, which is made by a gene called laminin. The merosin protein usually lies outside muscle cells and links them to the surrounding tissue. When merosin

WWW.BOOKBAZ.IR

is not produced, the muscle fibers degenerate soon after birth. A second gene called integrin is responsible for CMD in a few individuals but alterations in this gene are a rare cause of CMD. The gene responsible for Fukuyama CMD is FCMD and it is responsible for making a protein called fukutin whose function is not clear.

All of the muscular dystrophies are marked by muscle weakness as the major symptom. The distribution of symptoms, age of onset, and progression differ significantly. **Pain** is sometimes a symptom of each, usually due to the effects of weakness on joint position.

DUCHENNE MUSCULAR DYSTROPHY (DMD). A boy with Duchenne muscular dystrophy usually begins to show symptoms as a preschooler. The legs are affected first, making walking difficult and causing balance problems. Most patients walk three to six months later than expected and have difficulty running. Later on, a boy with DMD will push his hands against his knees to rise to a standing position, to compensate for leg weakness. About the same time, his calves will begin to enlarge, though with fibrous tissue rather than with muscle, and feel firm and rubbery; this condition gives DMD one of its alternate names, pseudohypertrophic muscular dystrophy. He will widen his stance to maintain balance, and walk with a waddling gait to advance his weakened legs. **Contractures** (permanent muscle tightening) usually begin by age five or six, most severely in the calf muscles. This pulls the foot down and back, forcing the boy to walk on tiptoes, and further decreases balance. Climbing stairs and rising unaided may become impossible by age nine or ten, and most boys use a wheelchair for mobility by the age of 12. Weakening of the trunk muscles around this age often leads to **scoliosis** (a side-to-side spine curvature) and **kyphosis** (a front-to-back curvature).

The most serious weakness of DMD is weakness of the diaphragm, the sheet of muscles at the top of the abdomen that perform the main work of breathing and coughing. Diaphragm weakness leads to reduced energy and stamina, and increased lung infection because of the inability to **cough** effectively. Young men with DMD often live into their twenties and beyond, provided they have mechanical ventilation assistance and good respiratory hygiene.

Among males with DMD, the incidence of **cardiomyopathy** (weakness of the heart muscle), increases steadily in teenage years. Almost all patients have cardiomyopathy after 18 years of age. It has also been shown that carrier females are at increased risk for cardiomyopathy and should also be screened.

About one-third of males with DMD experience specific learning disabilities, including difficulty learning by ear rather than by sight and difficulty paying attention to long lists of instructions. Individualized educational programs usually compensate well for these disabilities.

BECKER MUSCULAR DYSTROPHY (BMD). The symptoms of BMD usually appear in late childhood to early adulthood. Though the progression of symptoms may parallel that of DMD, the symptoms are usually milder and the course more variable. The same pattern of leg weakness, unsteadiness, and contractures occur later for the young man with BMD, often allowing independent walking into the twenties or early thirties. Scoliosis may occur, but is usually milder and progresses more slowly. Cardiomyopathy occurs more commonly in BMD. Problems may include irregular heartbeats (**arrhythmias**) and **congestive heart failure**. Symptoms may include **fatigue**, **shortness of breath**, chest pain, and **dizziness**. Respiratory weakness also occurs, and may lead to the need for mechanical ventilation.

EMERY-DREIFUSS MUSCULAR DYSTROPHY (EDMD). This type of muscular dystrophy usually begins in early childhood, often with contractures preceding muscle weakness. Weakness affects the shoulder and upper arm initially, along with the calf muscles, leading to foot–drop. Most men with EDMD survive into middle age, although an abnormality in the heart's rhythm (**heart block**) may be fatal if not treated with a pacemaker.

LIMB-GIRDLE MUSCULAR DYSTROPHY (LGMD). While there are several genes that cause the various types of LGMD, two major clinical forms of LGMD are usually recognized. A severe childhood form is similar in appearance to DMD, but is inherited as an autosomal recessive trait. Symptoms of adult-onset LGMD usually appear in a person's teens or twenties, and are marked by progressive weakness and wasting of the muscles closest to the trunk. Contractures may occur, and the ability to walk is usually lost about 20 years after onset. Some people with LGMD develop respiratory weakness that requires use of a ventilator. Life-span may be somewhat shortened. Autosomal dominant forms usually occur later in life and progress relatively slowly.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY (FSH). FSH varies in its severity and age of onset, even among members of the same family. Symptoms most commonly begin in the teens or early twenties, though infant or childhood onset is possible. Symptoms tend to be more severe in those with earlier onset.

The condition is named for the regions of the body most severely affected by the condition: muscles of the face (facio-), shoulders (scapulo-), and upper arms (humeral). Hips and legs may be affected as well. Children with FSH may develop partial or complete deafness.

The first symptom noticed is often difficulty lifting objects above the shoulders. The weakness may be greater on one side than the other. Shoulder weakness also causes the shoulder blades to jut backward, called scapular winging. Muscles in the upper arm often lose bulk sooner than those of the forearm, giving a "Popeye" appearance to the arms. Facial weakness may lead to loss of facial expression, difficulty closing the eyes completely, and inability to drink through a straw, blow up a balloon, or whistle. A person with FSH may not be able to wrinkle their forehead. Contracture of the calf muscles may cause foot-drop, leading to frequent tripping over curbs or rough spots. People with earlier onset often require a wheelchair for mobility, while those with later onset rarely do.

MYOTONIC DYSTROPHY. Symptoms of **myotonic dystrophy** include facial weakness and a slack jaw, drooping eyelids (**ptosis**), and muscle wasting in the forearms and calves. A person with myotonic dystrophy has difficulty relaxing his grasp, especially if the object is cold. Myotonic dystrophy affects heart muscle, causing arrhythmias and heart block, and the muscles of the digestive system, leading to motility disorders and **constipation**. Other body systems are affected as well; myotonic dystrophy may cause **cataracts**, retinal degeneration, mental deficiency, frontal balding, skin disorders, testicular atrophy, **sleep apnea**, and **insulin resistance**. An increased need or desire for sleep is common, as is diminished motivation. The condition is extremely variable; some individuals show profound weakness as a newborn (congenital myotonic dystrophy), others show intellectual disabilities in childhood, many show characteristic facial features and muscle wasting in adulthood, while the most mildly affected individuals show only cataracts in middle age with no other symptoms. Individuals with a severe form of mytonic dystropy typically have severe disabilities within 20 years of onset, although most do not require a wheelchair even late in life.

OCULOPHARYNGEAL MUSCULAR DYSTROPHY (OPMD). OPMD usually begins in a person's thirties or forties, with weakness in the muscles controlling the eyes and throat. Symptoms include drooping eyelids and difficulty swallowing (dysphagia). Weakness progresses to other muscles of the face, neck, and occasionally the upper limbs. Swallowing difficulty may cause aspiration, or the introduction of food or saliva into the airways. **Pneumonia** may follow.

DISTAL MUSCULAR DYSTROPHY (DD). DD usually begins in the twenties or thirties, with weakness in the hands, forearms, and lower legs. Difficulty with fine movements such as typing or fastening buttons may be the first symptoms. Symptoms progress slowly, and the condition usually does not affect life span.

CONGENITAL MUSCULAR DYSTROPHY (CMD). CMD is marked by severe muscle weakness from birth, with infants displaying "floppiness," very poor muscle tone, and they often have trouble moving their limbs or head against gravity. Mental function is normal but some are never able to walk. They may live into young adulthood or beyond. In contrast, children with Fukuyama CMD are rarely able to walk, and have severe ID. Most children with this type of CMD die in childhood.

Diagnosis

For most forms of muscular dystrophy, accurate diagnosis is not difficult when done by someone familiar with the range of conditions. There are exceptions, however. Even with a muscle biopsy, it may be difficult to distinguish between FSH and another muscle condition, **polymyositis**. Childhood-onset LGMD is often mistaken for the much more common DMD, especially when it occurs in boys. BMD with an early onset appears very similar to DMD, and a genetic test may be needed to accurately distinguish them. The muscular dystrophies may be confused with conditions involving the motor neurons, such as spinal muscular atrophy; conditions of the neuromuscular junction, such as **myasthenia gravis**; and other muscle conditions, as all involve generalized weakness of varying distribution.

Examination

The diagnosis of muscular dystrophy involves a careful medical history and a thorough physical exam to determine the distribution of symptoms and to rule out other causes. Family history may give important clues, since all the muscular dystrophies are genetic conditions (though no family history will be evident in the event of new mutations; in autosomal recessive inheritance, the family history may also be negative).

Tests

Lab tests may include:

- Blood level of the muscle enzyme creatine kinase (CK). CK levels rise in the blood due to muscle

WWW.BOOKBAZ.IR

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Becker muscular dystrophy (BMD)—A type of muscular dystrophy that affects older boys and men and usually follows a milder course than Duchenne muscular dystrophy.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the fetus. These cells are then tested for chromosome abnormalities or other genetic diseases.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Distal muscular dystrophy (DD)—A form of muscular dystrophy that usually begins in middle age or later, causing weakness in the muscles of the feet and hands.

Duchenne muscular dystrophy (DMD)—The most severe form of muscular dystrophy, which usually affects young boys and causes progressive muscle weakness, usually beginning in the legs.

Dystrophin—A protein that helps muscle tissue repair itself. Both Duchenne muscular dystrophy and Becker muscular dystrophy are caused by flaws in the gene that instructs the body how to make this protein.

Facioscapulohumeral muscular dystrophy (FSH)—A form of muscular dystrophy, also known as Landouzy-Dejerine condition, that begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles of the face, shoulders, and upper arms.

Limb-girdle muscular dystrophy (LGMD)—Form of muscular dystrophy that begins in late childhood to early adulthood and affects both men and women, causing weakness in the muscles around the hips and shoulders.

Myotonic dystrophy—A form of muscular dystrophy, also known as Steinert's condition, characterized by delay in the ability to relax muscles after forceful contraction, wasting of muscles, as well as other abnormalities.

Oculopharyngeal muscular dystrophy (OPMD)—Form of muscular dystrophy affecting adults of both sexes and causing weakness in the eye muscles and throat.

damage, and may be seen in some conditions even before symptoms appear.

- Muscle biopsy, in which a small piece of muscle tissue is removed for microscopic examination. Changes in the structure of muscle cells and presence of fibrous tissue or other aberrant structures are characteristic of different forms of muscular dystrophy. The muscle tissue can also be stained to detect the presence or absence of particular proteins, including dystrophin.
- Electromyogram (EMG). This electrical test is used to examine the response of the muscles to stimulation. Decreased response is seen in muscular dystrophy. Other characteristic changes are seen in DM.
- Genetic tests. Several of the muscular dystrophies can be positively identified by testing for the presence of the altered gene involved. Accurate genetic tests are available for DMD, BMD, DM, several forms of LGMD, and EDMD. Genetic testing for some of these conditions in future pregnancies of an affected individual or parents of an affected individual can be done before birth through amniocentesis or chorionic villus sampling. Prenatal testing can only be undertaken after the diagnosis in the affected individual has been genetically confirmed and the couple has been counseled regarding the risks of recurrence.
- Other specific tests as necessary. For EDMD, DMD and BMD, for example, an electrocardiogram may

be needed to test heart function, and hearing tests are performed for children with FSH.

Prenatal diagnosis (testing of the baby while in the womb) can be done for those types of muscular dystrophy where the specific disease-causing gene alteration has been identified in a previously affected family member. Prenatal diagnosis can be done utilizing DNA extracted from tissue obtained by **chorionic villus sampling** or **amniocentesis**.

Treatment

There is no specific treatment that can stop or reverse any form of muscular dytrophy. MD management is focused on improving muscle and joint function, and slowing muscle deterioration. Treatment also seeks to prevent the complications of weakness, including decreased mobility and dexterity, contractures, scoliosis, heart alterations, and respiratory insufficiency.

Physical therapy, regular stretching in particular, is used to maintain the range of motion of affected muscles and to prevent or delay contractures. Braces are used as well, especially on the ankles and feet to prevent tip–toeing. Full-leg braces may be used in children with DMD to prolong the period of independent walking. Strengthening other muscle groups to compensate for weakness may be possible if the affected muscles are few and isolated, as in the earlier stages of the milder muscular dystrophies. Regular, nonstrenuous **exercise** helps maintain general good health. Strenuous exercise is usually not recommended, since it may damage muscles further.

Occupational therapy also provides techniques and tools to compensate for the loss of strength and dexterity. Strategies may include modifications in the home, adaptive utensils and dressing aids, compensatory movements and positioning, wheelchair accessories, or communication aids.

Good **nutrition** helps to promote general health in all the muscular dystrophies. No special diet or supplement has been shown to be of use in any of the conditions. The weakness in the throat muscles seen especially in OPMD and later DMD may necessitate the use of a **gastrostomy** tube, inserted in the stomach to provide nutrition directly.

Drugs

For DMD, prednisone, a corticosteroid, has been shown to delay the progression of disease somewhat, for reasons that are still unclear. Some have reported improvement in strength and function in patients treated with a single dose. Improvement begins within ten days and plateaus after three months. Long-term benefit has not been demonstrated. Prednisone is also prescribed for BMD, though no controlled studies have tested its benefit.

Anticonvulsants, also known as antiepileptics, are also prescribed to control seizures and some muscle activity. Commonly used oral anticonvulsants include carbamazepine, phenytoin, clonazepam, gabapentin, topiramate, and felbamate. Respiratory infections are usually treated with **antibiotics**.

Alternatives

When contractures become more pronounced, tenotomy surgery may be performed. In this operation, the tendon of the contractured muscle is cut, and the limb is braced in its normal resting position while the tendon regrows. In FSH, surgical fixation of the scapula can help compensate for shoulder weakness. For a person with OPMD, surgical lifting of the eyelids may help compensate for weakened muscular control. For a person with DM, sleep apnea may be treated surgically to maintain an open airway. Scoliosis surgery is often needed in boys with DMD, but much less often in other muscular dystrophies. Surgery is recommended at a much lower degree of curvature for DMD than for scoliosis due to other conditions, since the decline in respiratory function in DMD makes surgery at a later time dangerous. In this surgery, the vertebrae are fused together to maintain the spine in the upright position. Steel rods are inserted at the time of operation to keep the spine rigid while the bones grow together.

When any type of surgery is performed in patients with muscular dystrophy, **anesthesia** must be carefully selected. People with MD are susceptible to a severe reaction, known as **malignant hyperthermia**, when given halothane anesthetic.

The arrhythmias of EDMD and BMD may be treatable with antiarrhythmia drugs. A pacemaker may be implanted if these do not provide adequate control. Heart transplants are increasingly common for men with BMD. A complete cardiac evaluation is recommended at least once in all carrier females of DMD and EDMD.

People who develop weakness of the diaphragm or other ventilatory muscles may require a mechanical ventilator to continue breathing deeply enough. Air may be administered through a nasal mask or mouthpiece, or through a tracheostomy tube, which is inserted through a surgical incision through the neck

WWW.BOOKBAZ.IR

and into the windpipe. Most people with muscular dystrophy do not need a tracheostomy, although some may prefer it to continual use of a mask or mouthpiece. Supplemental oxygen is not needed. Good hygiene of the lungs is critical for health and long-term survival of a person with weakened ventilatory muscles. Assisted cough techniques provide the strength needed to clear the airways of secretions; an assisted cough machine is also available and provides excellent results.

Clinical trials for the treatment of muscular dystrophies are sponsored by the National Institutes of Health (NIH) and other agencies. In 2009, NIH reported 23 on-going or recently completed studies. Some examples include the following:

- The evaluation of the efficacy of using far infrared radiation to manage muscular dystrophies (NCT00674843)
- The evaluation of whether a high-dose weekly course of prednisone therapy is safer than and at least as effective as daily dose therapy for people with Duchenne muscular dystrophy (NCT00110669)
- The study of the early signs and symptoms of fukutin-related protein (FKRP) muscular dystrophy to determine the reasons for differences in disease severity (NCT00313677)
- The evaluation of the safety and efficacy of antisense oligonucleotides in Duchenne muscular dystrophy (NCT00159250)

Clinical trial information is constantly updated by NIH and the most recent information on muscular dystrophy trials can be found at: http://clinicaltrials.gov/search/open/condition=%22Muscular+Dystrophies%22

Prognosis

The expected life span for a male with DMD has increased significantly. Most young men will live into their early or mid-twenties. Respiratory infections become an increasing problem as their breathing becomes weaker, and these infections are usually the cause of death.

The course of the other muscular dystrophies is more variable; expected life spans and degrees of disability are hard to predict, but may be related to age of onset and initial symptoms. Prediction is made more difficult because, as new genes are discovered, it is becoming clear that several of the dystrophies are not uniform disorders, but rather symptom groups caused by different genes.

People with dystrophies with significant heart involvement (BMD, EDMD, myotonic dystrophy) may nonetheless have almost normal life spans, provided that cardiac complications are monitored and treated aggressively. The respiratory involvement of BMD and LGMD similarly require careful and prompt treatment.

Prevention

There is no way to prevent any of the muscular dystrophies in a person who has the genes responsible for these disorders. Individuals with muscular dystrophy and their families may benefit from genetic counselling for information on the condition and recurrence risks for future pregnancies.

Nada Quercia, Msc, CCGC

Mushroom poisoning

Definition

Mushroom **poisoning** refers to the severe and often deadly effects of various toxins that are found in certain types of mushrooms. One type known as *Amanita phalloides*, appropriately called "death cap," accounts for the majority of cases. The toxins initially cause severe abdominal cramping, **vomiting**, and watery **diarrhea**, and then lead to liver and kidney failure.

Description

The highest reported incidences of mushroom poisoning occur in western Europe, where a popular pastime is amateur mushroom hunting. Since the 1970s, the United States has seen a marked increase in mushroom poisoning due to an increase in the popularity of "natural" foods, the use of mushrooms as recreational hallucinogens, and the gourmet qualities of wild mushrooms. About 90% of the deaths due to mushroom poisoning in the United States and western Europe result from eating *Amanita phalloides*. This

A poisonous mushroom, Amanita muscaria. *(Photo Researchers, Inc.)*

WWW.BOOKBAZ.IR

mushroom is recognized by its metallic green cap (the color may vary from light yellow to greenish brown), white gills (located under the cap), white stem, and bulb-shaped structure at the base of the stem. A pure white variety of this species also occurs. Poisoning results from ingestion of as few as one to three mushrooms. Higher death (mortality) rates of more than 50% occur in children under 10 years of age.

Causes and symptoms

Poisonous mushrooms contain at least two different types of toxins, each of which can cause death if taken in large enough quantities. Some of the toxins found in poisonous mushrooms are among the most potent ever discovered. One group of poisons, known as amatoxins, blocks the production of DNA, the basis of cell reproduction. This leads to the death of many cells, especially those that reproduce frequently such as in the liver, intestines, and kidney. Other mushroom poisons affect the proteins needed for muscle contraction, and therefore reduce the ability of certain muscle groups to perform.

Symptoms of *Amanita* poisoning occur in different stages or phases. These include:

- First phase. Abdominal cramping, nausea, vomiting, and severe watery diarrhea occur anywhere from 6-24 hours after eating the mushroom and last for about 24 hours. These intestinal symptoms can lead to dehydration and low blood pressure (hypotension).
- Second phase. A period of remission of symptoms that lasts 1-2 days. During this time, the patient feels better, but blood tests begin to show evidence of liver and kidney damage.
- Third phase. Liver and kidney failure develop at this point and either lead to death within about a week or recovery within 2-3 weeks.

Other symptoms are due to either a decrease in blood clotting factors that leads to internal bleeding or reduced muscle function, with the development of weakness and **paralysis**.

Diagnosis

In most cases, the fact that the patient has recently eaten wild mushrooms is the clue to the cause of symptoms. Moreover, the identification of any remaining mushrooms by a qualified mushroom specialist (mycologist) can be a key to diagnosis. When in doubt, the toxin known as alpha-amantin can be found in the blood, urine, or stomach contents of an individual who has ingested poisonous *Amanita* mushrooms.

Treatment

It is important to remember that there is no specific antidote for mushroom poisoning. However, several advances in therapy have decreased the death rate. Early replacement of lost body fluids has been a major factor in improving survival rates.

Therapy is aimed at decreasing the amount of toxin in the body. Initially, attempts are made to remove toxins from the upper gastrointestinal tract by inducing vomiting or by gastric lavage (stomach pumping). After that continuous aspiration of the upper portion of the small intestine through a **nasogastric tube** is done and oral charcoal (every four hours for 48 hours) is given to prevent absorption of toxin. These measures work best if started within six hours of ingestion.

In the United States, early removal of mushroom poison by way of an artificial kidney machine (dialysis) has become part of the treatment program. This is combined with the correction of any imbalances of salts (electrolytes) dissolved in the blood, such as **sodium** or potassium. An enzyme called thioctic acid and **corticosteroids** also appear to be beneficial, as well as high doses of penicillin. In Europe, a chemical taken from the milk thistle plant, *Silybum marianum*, is also part of treatment. When liver failure develops, **liver transplantation** may be the only treatment option.

Prognosis

The mortality rate has decreased with improved and rapid treatment. However, according to some medical reports death still occurs in 20-30% of cases, with a higher mortality rate of 50% in children less than 10 years old.

Prevention

The most important factor in preventing mushroom poisoning is to avoid eating wild or noncultivated mushrooms. For anyone not expert in mushroom identification, there are generally no easily recognizable differences between nonpoisonous and poisonous mushrooms. It is also important to remember that most mushroom poisons are not destroyed or deactivated by cooking, canning, freezing, drying, or other means of food preparation.

Music therapy

Definition

Music therapy is a technique of complementary medicine that uses music prescribed in a skilled manner by trained therapists. Programs are designed to help patients overcome physical, emotional, intellectual, and social challenges. Applications range from improving the well being of geriatric patients in nursing homes to lowering the **stress** level and **pain** of women in labor. Music therapy is used in many settings, including schools, **rehabilitation** centers, hospitals, hospices, nursing homes, community centers, and sometimes even in the home.

Purpose

Music can be beneficial for anyone. Although it can be used therapeutically for people who have physical, emotional, social, or cognitive deficits, even those who are healthy can use music to relax, reduce stress, improve mood, or to accompany **exercise**. There are no potentially harmful or toxic effects. Music therapists help their patients achieve a number of goals through music, including improvement of communication, academic performance, attention span, and motor skills. They may also assist with behavioral therapy and **pain management**.

Demographics

There are about 5,000 board certified music therapists in the United States. The field is growing rapidly as an increasing number of both inpatient and outpatient healthcare settings incorporate music therapy into their treatment modalities.

Description

Origins

Music has been used throughout human history to express and affect human emotion. In biblical accounts, King Saul was reportedly soothed by David's harp music, and the ancient Greeks expressed thoughts about music having healing effects as well. Many cultures are steeped in musical traditions. Music can change mood, have stimulant or sedative effects, and alter physiologic processes such as heart rate and breathing. The apparent health benefits of music to patients in Veterans Administration hospitals following World War II led to its being studied and formalized as a complementary healing practice. Musicians were hired to continue working in the hospitals. Degrees in music therapy became available in the late 1940s, and in 1950, the first professional association of music therapists was formed in the United States. The National Association of Music Therapy merged with the American Association of Music Therapy in 1998 to become the American Music Therapy Association.

Physical effects

Brain function physically changes in response to music. The rhythm can guide the body into breathing in slower, deeper patterns that have a calming effect. Heart rate and blood pressure are also responsive to the types of music that are listened to. The speed of the heartbeat tends to speed or slow depending on the volume and speed of the auditory stimulus. Louder and faster noises tend to raise both heart rate and blood pressure; slower, softer, and more regular tones produce the opposite result. Music can also relieve muscle tension and improve motor skills. It is often used to help rebuild physical patterning skills in rehabilitation clinics. Levels of endorphins, natural pain relievers, are increased while listening to music, and levels of stress hormones are decreased. This latter effect may partially explain the ability of music to improve immune function. A study at Michigan State University showed that even 15 minutes of exposure to music could increase interleukin-1 levels, a consequence which also heightens immunity.

Mental effects

Depending on the type and style of sound, music can either sharpen mental acuity or assist in relaxation. Memory and learning can be enhanced, and this use had good results in children with learning disabilities. This effect may also be partially due to increased concentration that many people have while listening to music. Better productivity is another outcome of an improved ability to concentrate. The term *Mozart effect* was coined after a study showed that college students performed better on math problems when listening to classical music.

WWW.BOOKBAZ.IR

KEY TERMS

Adjunctive—Refers to a form of treatment that is not strictly necessary to a therapy regimen but is helpful. Music therapy is an example of an adjunctive treatment.

Entrainment—The patterning of body processes and movements to the rhythm of music.

Physiologic—Refers to physiology, particularly normal, healthy, physical functioning.

Emotional effects

The ability of music to influence human emotion is well known and is used extensively by moviemakers. A variety of musical moods may be used to create feelings of calmness, tension, excitement, or romance. Lullabies have long been popular for soothing babies to sleep. Music can also be used to express emotion nonverbally, which can be a very valuable therapeutic tool in some settings.

Goals

Music is used to form a relationship between the therapist and the patient. The music therapist sets goals on an individual basis, depending on the reasons for treatment, and selects specific activities and exercises to help the patient progress. Objectives may include development of communication, cognitive, motor, emotional, and social skills. Some of the techniques used to achieve this are singing, listening, instrumental music, composition, creative movement, **guided imagery**, and other methods as appropriate. Other disciplines may be integrated as well, such as dance, art, and psychology. Patients may develop musical abilities as a result of therapy, but this is not a major concern. The primary aim is to improve the patient's ability to function.

Techniques

Learning to play an instrument is an excellent musical activity for developing motor skills in individuals with developmental delays, brain injuries, or other motor impairment. It is also an exercise in impulse control and group cooperation. Creative movement is another activity that can help to improve coordination, as well as strength, balance, and gait. Improvisation facilitates the nonverbal expression of emotion. It encourages socialization and communication about feelings as well. Singing develops articulation, rhythm, and breath control. Remembering lyrics and melody is an exercise in sequencing for **stroke** victims and others who may be intellectually impaired. Composition of words and music is one avenue available to assist the patient in working through fears and negative feelings. Listening is an excellent way to practice attending and remembering. It may also make the patient aware of memories and emotions that need to be acknowledged and perhaps talked about. Singing and discussion is a similar method, which is used with some patient populations to encourage dialogue. Guided Imagery and Music (GIM) is a very popular technique developed by music therapist Helen Bonny. Listening to music is used as a path to invoke emotions, picture, and symbols from the patient. This is a bridge to the exploration and expression of feelings.

Music and children

The sensory stimulation and playful nature of music can help to develop a child's ability to express emotion, communicate, and develop rhythmic movement. There is also some evidence to show that speech and language skills can be improved through the stimulation of both hemispheres of the brain. Just as with adults, appropriately selected music can decrease stress, **anxiety**, and pain. Music therapy in a hospital environment with those who are sick, **preparing for surgery**, or recovering postoperatively is appropriate and beneficial. Children can also experience improved self-esteem through musical activities that allow them to succeed.

Newborns may enjoy even greater benefits from music. Premature infants experience more rapid weight gain and an earlier **discharge from the hospital** than their peers who are not exposed to music. There is also anecdotal evidence of improved cognitive function in premature infants from listening to music.

Music and rehabilitation

Patients with brain damage from stroke, **traumatic brain injury**, or other neurologic conditions have been shown to exhibit significant improvement as a result of music therapy. This is theorized to be partially the result of entrainment, which is the synchronization of movement with the rhythm of the music. Consistent practice leads to gains in motor skill ability and efficiency. Cognitive processes and language skills often benefit from appropriate musical intervention.

Music therapy has also shown effectiveness in rehabilitating the hearing of children and adults who have had cochlear implant surgery to treat impaired hearing. Young children who have never heard sounds

face a lengthy rehabilitation in order to learn how to interpret sound and form speech. Music therapy can serve as a bridge between non verbal communication and the new sounds that toddlers are hearing and processing into language. In adults with **cochlear implants**, music therapy can offer relaxation to minimize distortion among new sounds, and cues to remembering old sounds. Individualized music therapy is also used to reduce noise levels in people with **tinnitus**, or ringing in the ears.

Music and the elderly

The geriatric population can be particularly prone to anxiety and depression, particularly in nursing home residents. Chronic diseases causing pain are also not uncommon in this setting. Music is an excellent outlet to provide enjoyment, relaxation, relief from pain, and an opportunity to socialize and reminisce about music that has had special importance to the individual. It can have a striking effect on patients with Alzheimer's disease, even sometimes allowing them to focus and become more responsive for a time. Music has also been observed to decrease the agitation that is so common with this disease. One study shows that elderly people who play a musical instrument are more physically and emotionally fit as they age than their nonmusical peers are.

Music and psychiatric disorders

Music can be an effective tool for treating the mentally or emotionally ill. **Autism** is one disorder that has been particularly researched. Music therapy has enabled some autistic children to relate to others and have improved learning skills. Substance abuse, **schizophrenia**, **paranoia**, and disorders of personality, anxiety, and affect are all conditions that may be benefited by music therapy. In these groups, participation and social interaction are promoted through music. Reality orientation is improved. Patients are helped to develop coping skills, reduce stress, and express their feelings.

In the treatment of psychotic disorders, however, the benefits of music therapy appear to be limited. One study of patients diagnosed with schizophrenia or schizoaffective **psychosis** found that while music therapy improved the patients' social relationships, these benefits were relatively short-lived.

Music and hospice care

Pain, anxiety, and depression are major concerns with patients who are terminally ill, whether they are in hospice or not. Music can provide some relief from pain, through release of endorphins and promotion of relaxation. It can also provide an opportunity for the patient to reminisce and talk about the fears that are associated with **death and dying**. Music may help regulate the rapid breathing of a patient who is anxious, and soothe the mind. The Chalice of Repose project, headquartered at St. Patrick Hospital in Missoula, Montana, attends and nurtures dying patients through the use of music, in a practice they called music-thanatology by developer Therese Schroeder-Sheker. Practitioners in this program work to relieve suffering through music prescribed for the individual patient.

Music and gynecologic procedures

Research has proven that women require less pharmaceutical pain relief during labor if they make use of music. Listening to music that is familiar and associated with positive imagery is the most helpful. During early labor, music will promote relaxation. Maternal movement is helpful to get the baby into a proper birthing position and dilate the cervix. Enjoying some "music to move by" can encourage the mother to stay active for as long as possible during labor. The rhythmic auditory stimulation may also prompt the body to release endorphins, which are a natural form of pain relief. Many women select different styles of music for each stage of labor, with a more intense, or faster-moving piece feeling like a natural accompaniment to the more difficult parts of labor. Instrumental music is often preferred.

The benefits of music therapy during **childbirth** have also been shown to apply to other surgical procedures. Women who have listened to music tapes during **gynecologic surgery** have more restful sleep following the procedure and less postoperative soreness.

Precautions

Patients making use of music therapy should not discontinue medications or therapies prescribed by other health providers without prior consultation.

Research and general acceptance

There is little disagreement among physicians that music can be of some benefit for patients, although the extent of its effects on physical well-being is not as well acknowledged in the medical community. Acceptance of music therapy as an adjunctive treatment modality is increasing, however, due to the growing diversity of patient populations receiving music therapy. Research

WWW.BOOKBAZ.IR

has shown that listening to music can decrease anxiety, pain, and recovery time. There are also good data for the specific subpopulations discussed. A therapist referral can be made through the AMTA.

Training and certification

Music therapists are themselves often talented musicians; they also study the ways in which music can be applied to specific groups and circumstances. Coursework includes classes regarding music history and performance, behavioral science, and education. The American Music Therapy Association dictates what classes must be included in order for a music therapy program to be certified. There are approximately 70 colleges with approved curricula. A six-month internship follows the completion of the formal music therapy program, and the graduate is then able to take a national board exam to gain certification.

Mutism

Definition

Mutism is a rare childhood condition characterized by a consistent failure to speak in situations where talking is expected. As of 2010, the childhood disorder was more often called selective mutism or SM to distinguish it from akinetic mutism, a brain disorder in which the patient does not move about as well, as not being able to speak. Akinetic mutism is caused by severe damage to the frontal lobe of the brain. SM, in contrast, is an **anxiety** disorder that affects behavior rather than the structure and functioning of the brain itself. A child with selective mutism has the ability to converse normally, and does so, for example, in the home, but consistently fails to speak in such situations as at school or with strangers. The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM–IV), classifies selective mutism under the general category of "disorders usually first diagnosed in infancy, childhood, or adolescence."

Demographics

It was estimated in the past that one in every 1,000 school-age children in North America is affected by selective mutism. However, a study carried out by the American Academy of Child and Adolescent Psychiatry (AACAP) reported in 2002 that a more accurate figure is seven children in every 1,000. DSM–IV states that the disorder "is apparently rare and is found in fewer than one percent of individuals seen in mental health settings." The condition is more common in girls, with a sex ratio of 2–2.5 females to one male. So far as is known, the condition is equally common in all racial and ethnic groups.

Description

Experts believe that selective mutism is associated with anxiety and fear in social situations such as in school or in the company of adults. It is, therefore, often considered a type of social phobia. Selective

mutism is not a communication disorder because affected children can converse normally in some situations. It is not a developmental disorder because their ability to talk when they choose to do so is appropriate for their age level. This problem has been linked to anxiety, and one of the major ways in which both children and adults attempt to cope with anxiety is by avoiding whatever provokes the anxiety. The onset of selective mutism is often abrupt, occurring after the child has first entered school or suffered some other public humiliation.

Affected children are typically shy and are especially so in the presence of strangers and unfamiliar surroundings or situations. However, the behaviors of children with this condition go beyond **shyness**. The condition becomes progressive in some cases, meaning that the child gradually stops talking to everyone, including his or her own parents.

Selective mutism was originally termed "elective mutism" when it was first listed in the third (1980) edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM–III). Doctors at the time thought that children with the disorder chose to remain silent when they could speak. It is now recognized that the inability to speak is involuntary and does not reflect stubbornness or opposition. The change from "elective" to "selective" mutism was made in the fourth edition (1994) of DSM (DSM–IV) to correct the misconception that children with SM are simply defiant and willful. They actually have a lower rate of oppositional disorder than their school–age peers.

Risk factors

Known risk factors for SM include a family history of **anxiety disorders**, particularly social phobia or **generalized anxiety disorder** (GAD). Some researchers report that rejection by peers or separation from caregivers due to severe illness or hospitalization in early childhood is also risk factors. According to the Selective Mutism Foundation (SMF), however, physical or emotional **abuse** within the family or family dysfunction does not usually cause of selective mutism.

Causes and symptoms

Mutism is believed to arise from anxiety experienced in social situations in which a child may be called upon to speak. Refusing to speak, or speaking in a whisper, spares the child from the possible humiliation or embarrassment of "saying the wrong thing." When asked a direct question by teachers, for example, the affected child may act as if he or she is unable to answer. Some children may communicate via gestures, nodding, or very brief utterances. Additional features may include excessive shyness, oppositional behavior, and impaired learning at school.

KEY TERMS

Amygdala—An almond–shaped structure found deep within each medial temporal lobe of the brain that plays a primary role in the processing and memory of emotional experiences.

Behavior modification—A form of therapy that uses rewards to reinforce desired behavior. An example would be to give a child a piece of chocolate for grooming himself or herself appropriately.

Oppositional defiant disorder—A childhood behavioral disorder characterized by an ongoing pattern of disobedient, hostile, and defiant behavior toward authority figures that goes beyond the bounds of normal childhood conduct.

Sensory integration dysfunction—A neurological disorder in which a person has trouble processing and integrating all the information relayed to the brain by the various senses. Some researchers think that it is a possible cause of selective mutism.

Some possible genetic or inborn causes of SM are currently under investigation. Some children appear to have an inborn susceptibility to high anxiety levels. Another theory maintains that children with SM have an overly excitable amygdala, an almond–shaped structure in the brain that governs the so–called fight–or–flight response. Still another theory holds that children with selective mutism suffer from sensory integration dysfunction, a neurological disorder that affects one' ability to process certain information coming from the senses. The resulting difficulties lead to anxiety, which in turn causes the child to "shut down" and stop talking to others.

Diagnosis

Selective mutism is usually diagnosed before a child is five years old, most often about the time the child starts school. The diagnosis is not always easy to make because the signs and symptoms can be confused with those of autism—particularly when the child is shy around the diagnostician. It is also important for the examiner to rule out cultural factors, such as recent immigration and little exposure to spoken English or recent exposure to a traumatic event of some kind. It is not unusual for children to stop speaking temporarily

WWW.BOOKBAZ.IR

after witnessing a murder, serious accident, or other frightening event. This type of mutism is transient, however, and usually clears up after a few weeks. For this reason DSM–IV specifies that the child's mutism must have lasted for a month or longer to meet the diagnostic criteria for SM. Other disorders that must be ruled out include **schizophrenia**, a pervasive developmental disorder (PDD), or **stuttering** or another communication disorder. Older children or teenagers may be asked about their **caffeine** intake, as heavy consumption of **energy drinks** can lead to jitteriness and other symptoms that resemble those of anxiety disorders.

Examination

The American Speech–Language–Hearing Association (ASHA) recomments that children who may suffer from SM should be evaluated by a speech–language pathologist in addition to a pediatrician and a child psychiatrist or psychologist. A complete diagnostic workup will include a number of different reviews, interviews, and tests:

- Educational review. The child's school reports, standardized test results, and teacher comments will be reviewed.
- Child Autism Rating Scale (CARS). This is a test administered by a licensed clinical psychologist to rule out autism or PDD.
- Parent/family interview. This interview is intended to gather information on such factors as language problems, family history of anxiety disorders (if any), general level of family functioning, and information from the parents about the history of the child's symptoms at home.
- Hearing test. This test is done to rule out hearing disorders or chronic middle ear infections as factors.
- Oral–motor examination. This is an examination of the strength and coordination of the muscles in the child's lips, jaws, and tongue.
- Speech and language evaluation. This part of the diagnostic workup looks at the child's ability to understand language, his or her patterns of verbal and nonverbal communication, and his or her ability to tell a simple story. If the child has difficulty communicating with the speech–language pathologist, the parents may be asked to make a videotape of the child talking at home.

Treatment

There is no single pattern of treatment for SM. Therapy is highly individualized, with the child's age, family situation, and overall health being taken into account. It is, however, important to start treatment as soon as possible after diagnosis, because children do not grow out of SM. In fact, their anxiety levels typically increase the longer the disorder goes untreated.

Most therapists will use a combination of behavioral strategies in treating a child with selective mutism. The most commonly employed behavioral techniques include:

- Stimulus fading. Stimulus fading refers to a technique in which the patient is brought into a controlled environment with someone with whom they are at ease and can communicate. Stimulus fading is usually used only with younger children, because older children and adolescents can quickly recognize it as a technique to get them to speak.
- Shaping. In shaping, the therapist gives the child positive reinforcement, first for interacting without speech, then for making sounds, then for making fully formed words.
- Self–modeling. In self–modeling, the therapist, parents, or teachers make videotapes of the child successfully communicating at home (or communicating successfully elsewhere, as with playmates). The child is then encouraged to watch him- or herself succeeding in speaking normally, as a way of boosting self-confidence and carrying over speaking normally into the classroom or other setting in which mutism occurs.
- Role–playing. This technique can be helpful in encouraging the child to feel comfortable in a variety of different settings with different participants.

Drugs

The use of drugs in treating SM is controversial. Some doctors recommend low doses of antidepressants like fluoxetine (Prozac) or sertraline (Zoloft) to lower the child's anxiety level and speed up the process of **speech therapy**. If an antidepressant is used, it is not given for longer than nine to 12 months, and it is more likely to be given to older children or teenagers than to younger children. Other doctors refuse to give medications to children with SM because of the risk of possible side effects. In any case, drugs should never be used as the sole treatment of selective mutism.

Prognosis

The prognosis for selective mutism varies considerably, although the overall prognosis is fair–to–good as of 2010. In general, children diagnosed before age 10 do better than those diagnosed and treated after age 12. Children with concurrent social phobia do not do

as well as those with selective mutism alone. Individuals with SM who are not diagnosed or treated until they are adolescents have the poorest prognosis, most likely because they have fewer overall communication skills in social settings than children who were treated at younger ages. Selective mutism was one of the disorders that were diagnosed in Seung–hui Cho, the student responsible for the Virginia Tech massacre of 2007. Cho was not diagnosed with SM or treated for it until he was in eighth grade. He was treated for three years for the disorder but refused further therapy during his junior year of high school.

Prevention

Selective mutism is difficult to prevent because relatively little is known about its causes or risk factors. The best preventive approach is regular checkups for possible hearing problems in young children and more extensive evaluation as soon as a speech problem is present.

Myasthenia gravis

Definition

Myasthenia gravis is an autoimmune disease that causes muscle weakness.

Description

Myasthenia gravis (MG) affects the neuromuscular junction, interrupting the communication between nerve and muscle, and thereby causing weakness. Individuals with MG may have difficulty moving their eyes, walking, speaking clearly, swallowing, and even breathing, depending on the severity and distribution of weakness.

WWW.BOOKBAZ.IR

Increased weakness with exertion and improvement with rest are a characteristic features of MG.

About 30,000 people in the United States are affected by MG. It can occur at any age, but is most common in women who are in their late teens and early twenties, and in men in their sixties and seventies.

Causes and symptoms

Myasthenia gravis is an autoimmune disease, meaning it is caused by the body's own immune system. In MG, the immune system attacks a receptor on the surface of muscle cells. This prevents the muscle from receiving the nerve impulses that normally make it respond. MG affects "voluntary" muscles, which are those muscles under conscious control responsible for movement. It does not affect heart muscle or the "smooth" muscle found in the digestive system and other internal organs.

A muscle is stimulated to contract when the nerve cell controlling it releases acetylcholine molecules onto its surface. The acetylcholine lands on a muscle protein called the acetylcholine receptor. This leads to rapid chemical changes in the muscle which cause it to contract. Acetylcholine is then broken down by acetylcholinesterase enzyme, to prevent further stimulation.

In MG, immune cells create antibodies against the acetylcholine receptor. Antibodies are proteins normally involved in fighting infection. When these antibodies attach to the receptor, they prevent it from receiving acetylcholine, decreasing the ability of the muscle to respond to stimulation.

Why the immune system creates these self-reactive "autoantibodies" is unknown, although there are several hypotheses:

- During fetal development, the immune system generates many B cells that can make autoantibodies, but B cells that could harm the body's own tissues are screened out and destroyed before birth. It is possible that the stage is set for MG when some of these cells escape detection.
- Genes controlling other parts of the immune system, called MHC genes, appear to influence how susceptible a person is to developing autoimmune disease.
- Infection may trigger some cases of MG. When activated, the immune system may mistake portions of the acetylcholine receptor for portions of an invading virus, though no candidate virus has yet been identified conclusively.
- About 10% of those with MG also have thymomas, or benign tumors of the thymus gland. The thymus is a principal organ of the immune system, and researchers speculate that thymic irregularities are involved in the progression of MG.

Some or all of these factors (developmental, genetic, infectious, and thymic) may interact to create the autoimmune reaction.

The earliest symptoms of MG often result from weakness of the extraocular muscles, which control eye movements. Symptoms involving the eye (ocular symptoms) include double vision (diplopia), especially when not gazing straight ahead, and difficulty raising the eyelids (**ptosis**). Individuals with ptosis may need to tilt their head back to see. Eye-related symptoms remain the only symptoms for about 15% of MG patients. Another common early symptom is difficulty chewing and swallowing, due to weakness in the bulbar muscles, which are in the mouth and throat. **Choking** becomes more likely, especially with food that requires extensive chewing.

Weakness usually becomes more widespread within several months of the first symptoms, reaching its maximum within a year in two-thirds of patients. Weakness may involve muscles of the arms, legs, neck, trunk, and face, and affect the ability to lift objects, walk, hold the head up, and speak.

Symptoms of MG become worse upon exertion, and better with rest. Heat, including heat from the sun, hot showers, and hot drinks, may increase weakness. Infection and **stress** may worsen symptoms. Symptoms may vary from day to day and month to month, with intervals of no weakness interspersed with a progressive decline in strength.

"Myasthenic crisis" may occur, in which the breathing muscles become too weak to provide adequate respiration. Symptoms include weak and shallow breathing, **shortness of breath**, pale or bluish skin color, and a racing heart. Myasthenic crisis is an emergency condition requiring immediate treatment. In patients treated with anticholinesterase agents, myasthenic crisis must be differentiated from cholinergic crisis related to overmedication.

Pregnancy worsens MG in about one-third of women, has no effect in one third, and improves symptoms in another third. About 12% of infants born to women with MG have "neonatal myasthenia," a temporary but potentially life-threatening condition. It is caused by the transfer of maternal antibodies into the fetal circulation just before birth. Symptoms include weakness, floppiness, feeble cry, and difficulty feeding. The infant may have difficulty breathing, requiring the use of a ventilator. Neonatal myasthenia usually clears up within a month.

Diagnosis

Myasthenia gravis is often diagnosed accurately by a careful medical history and a neuromuscular exam, but several tests are used to confirm the diagnosis. Other conditions causing worsening of bulbar and skeletal muscles must be considered, including drug-induced myasthenia, thyroid disease, Lambert-Eaton myasthenic syndrome, **botulism**, and inherited muscular dystrophies.

MG causes characteristic changes in the electrical responses of muscles that may be observed with an electromyogram, which measures muscular response to electrical stimulation. Repetitive nerve stimulation leads to reduction in the height of the measured muscle response, reflecting the muscle's tendency to become fatigued.

Blood tests may confirm the presence of the antibody to the acetylcholine receptor, though up to a quarter of MG patients will not have detectable levels. A chest x ray or chest computed tomography scan (CT scan) may be performed to look for **thymoma**.

Treatment

While there is no cure for myasthenia gravis, there are a number of treatments that effectively control symptoms in most people.

Edrophonium (Tensilon) blocks the action of acetylcholinesterase, prolonging the effect of acetylcholine and increasing strength. An injection of edrophonium rapidly leads to a marked improvement in most people with MG. An alternate drug, neostigmine, may also be used.

Pyridostigmine (Mestinon) is usually the first drug tried. Like edrophonium, pyridostigmine blocks acetylcholinesterase. It is longer-acting, taken by mouth, and well-tolerated. Loss of responsiveness and disease progression combine to eventually make pyridostigmine ineffective in tolerable doses in many patients.

Thymectomy, or removal of the thymus gland, has increasingly become standard treatment for MG. Up to 85% of people with MG improve after thymectomy, with complete remission eventually seen in about 30%. The improvement may take months or even several years to fully develop. Thymectomy is not usually recommended for children with MG, since the thymus continues to play an important immune role throughout childhood.

Immune-suppressing drugs are used to treat MG if response to pyridostigmine and thymectomy are not adequate. Drugs include **corticosteroids** such as prednisone, and the non-steroids azathioprine (Imuran) and cyclosporine (Sandimmune).

Plasma exchange may be performed to treat myasthenic crisis or to improve very weak patients before thymectomy. In this procedure, blood plasma is removed and replaced with purified plasma free of autoantibodies. It can produce a temporary improvement in symptoms, but is too expensive for long-term treatment. Another blood treatment, intravenous immunoglobulin therapy, is also used for myasthenic crisis. In this procedure, large quantities of purified immune proteins (immunoglobulins) are injected. For unknown reasons, this leads to symptomatic improvement in up to 85% of patients. It is also too expensive for long-term treatment.

People with weakness of the bulbar muscles may need to eat softer foods that are easier to chew and swallow. In more severe cases, it may be necessary to obtain **nutrition** through a feeding tube placed into the stomach (**gastrostomy** tube).

Prognosis

Most people with MG can be treated successfully enough to prevent their condition from becoming debilitating. In some cases, however, symptoms may worsen even with vigorous treatment, leading to generalized weakness and disability. MG rarely causes early death except from myasthenic crisis.

Prevention

There is no known way to prevent myasthenia gravis. Thymectomy improves symptoms significantly in many patients and relieves them entirely in some. Avoiding heat can help minimize symptoms.

Some drugs should be avoided by people with MG because they interfere with normal neuromuscular function.

Drugs to be avoided or used with caution include:

- Many types of antibiotics, including erythromycin, streptomycin, and ampicillin
- Some cardiovascular drugs, including Verapamil, betaxolol, and propranolol
- Some drugs used in psychiatric conditions, including chlorpromazine, clozapine, and lithium

Many other drugs may worsen symptoms as well, so patients should check with the doctor who treats their MG before taking any new drugs.

A Medic-Alert card or bracelet provides an important source of information to emergency providers about the special situation of a person with MG. They are available from healthcare providers.

WWW.BOOKBAZ.IR

KEY TERMS

Antibody—An immune protein normally used by the body for combating infection and which is made by B cells.

Autoantibody—An antibody that reacts against part of the self.

Autoimmune disease—A disease caused by a reaction of the body's immune system.

Bulbar muscles—Muscles that control chewing, swallowing, and speaking.

Neuromuscular junction—The site at which nerve impulses are transmitted to muscles.

Pyridostigmine bromide (Mestinon)—An anticholinesterase drug used in treating myasthenia gravis.

Tensilon test—A test for diagnosing myasthenia gravis. Tensilon is injected into a vein and, if the person has MG, their muscle strength will improve for about five minutes.

Thymus gland—A small gland located just above the heart, involved in immune system development.

Richard Robinson

Mycetoma

Definition

Mycetoma, or maduromycosis, is a slow-growing bacterial or fungal infection focused in one area of the body, usually the foot. For this reason—and because the first medical reports were from doctors in Madura, India—an alternate name for the disease is Madura foot. The infection is characterized by an abnormal tissue mass beneath the skin, formation of cavities within the mass, and a fluid discharge. As the infection progresses, it affects the muscles and bones; at this advanced stage, disability may result.

Description

Although the bacteria and fungi that cause mycetoma are found in soil worldwide, the disease occurs mainly in tropical areas in India, Africa, South America, Central America, and Southeast Asia. Mycetoma is an uncommon disease, affecting an unknown number of people annually.

There are more than 30 species of bacteria and fungi that can cause mycetoma. Bacteria or fungi can be introduced into the body through a relatively minor skin wound. The disease advances slowly over months or years, typically with minimal **pain**. When pain is experienced, it is usually due to secondary infections or bone involvement. Although it is rarely fatal, mycetoma causes deformities and potential disability at its advanced stage.

Causes and symptoms

Owing to a wound, bacteria or fungi gain entry into the skin. Approximately one month or more after the injury, a nodule forms under the skin surface. The nodule is painless, even as it increases in size over the following months. Eventually, the nodule forms a tumor, or mass of abnormal tissue. The tumor contains cavities—called sinuses—that discharge blood- or pus-tainted fluid. The fluid also contains tiny grains, less than two-thousandths of an inch in size. The color of these grains depends on the type of bacteria or fungi causing the infection.

As the infection continues, surrounding tissue becomes involved, with an accumulation of scarring and loss of function. The infection can extend to the bone, causing inflammation, pain, and severe damage. Mycetoma may be complicated by secondary infections, in which new bacteria become established in the area and cause an additional set of problems.

Diagnosis

The primary symptoms of a tumor, sinuses, and grain-flecked discharge often provide enough information to diagnose mycetoma. In the early stages, prior to sinus formation, diagnosis may be more difficult and a biopsy, or microscopic examination of the tissue, may be necessary. If bone involvement is suspected, the area is x rayed to determine the extent of the damage. The species of bacteria or fungi at the root of the infection is identified by staining the discharge grains and inspecting them with a microscope.

KEY TERMS

Biopsy—A medical procedure in which a small piece of tissue is surgically removed for microscopic examination.

Grains—Flecks of hardened material such as bacteria or fungi spores.

Nodule—A hardened area or knot sometimes associated with infection.

Secondary infection—Illness caused by new bacteria, viruses, or fungi becoming established in the wake of an initial infection.

Sinuses—Cavities or hollow areas.

Tumor—A mass or clump of abnormal tissue, not necessarily caused by a cancer.

Treatment

Combating mycetoma requires both surgery and drug therapy. Surgery usually consists of removing the tumor and a portion of the surrounding tissue. If the infection is extensive, **amputation** is sometimes necessary. Drug therapy is recommended in conjunction with surgery. The specific prescription depends on the type of bacteria or fungi causing the disease. Common medicines include antifungal drugs, such as ketoconazole and **antibiotics** (streptomycin sulfate, amikacin, sulfamethoxazole, penicillin, and rifampin).

Prognosis

Recovery from mycetoma may take months or years, and the infection recurs after surgery in at least 20% of cases. Drug therapy can reduce the chances of a re-established infection. The extent of deformity or disability depends on the severity of infection; the more deeply entrenched the infection, the greater the damage. By itself, mycetoma is rarely fatal, but secondary infections can be fatal.

Prevention

Mycetoma is a rare condition that is not contagious.

Mycobacterial infections, atypical

Definition

Atypical mycobacterial infections are infections caused by several types of mycobacteria similar to the germ that causes **tuberculosis**. These atypical mycobacterial infections are a frequent complication in patients with human **immunodeficiency** virus (HIV) infection or **AIDS**.

Description

Mycobacteria are a group of rod-shaped bacteria that cause several diseases, among them **leprosy** and tuberculosis. For some time, scientists have known of bacteria that are similar to *Mycobacterium tuberculosis,* the cause of tuberculosis, but that grow and act differently. When tuberculosis was a much more widespread problem and **microbiology** was much less able to tell the difference between similar microbes, these atypical mycobacteria were ignored. Today, they have been classified as members of the same species and called atypical (or nontuberculosis) mycobacteria.

Although the medical profession has known about these atypical infections for a long time, they were not considered a serious problem until the early 1980s. It was then that many of these atypical infections were noticed among homosexuals and intravenous drug users in New York City. These bacteria rarely cause infection in humans other than those with HIV or AIDS.

Causes and symptoms

Although there are more than a dozen species of atypical mycobacteria, the two most common are *Mycobacterium kansasii* and *M. avium-intracellulare*. These microbes are found in many places in the environment: tap water, fresh and ocean water, milk, bird droppings, soil, and house dust. The manner in which these bacteria are transmitted is not completely understood. There is no evidence that they are transmitted from person to person.

M. avium-intracellulare (MAC or MAI) is a rare cause of lung disease in otherwise healthy humans but a frequent cause of infection among those whose resistance has been lowered by another disorder (opportunistic infection). According to some experts, MAC infection is an almost inevitable complication of HIV. The infection is caused by one of two similar organisms, *M. avium* and *M. intracellulare*.

WWW.BOOKBAZ.IR

AIDS patients are almost always attacked by these mycobacteria. Once inside the body, the atypical mycobacterial organisms colonize and grow in the lungs like tuberculosis. Because AIDS patients have a poorly functioning immune system, the microbes multiply because they are not stopped by the body's normal response to infection. Once they have colonized the lungs, the organisms enter the bloodstream and spread throughout the body, affecting almost every organ. These devastating infections can invade the lymph nodes, liver, spleen, bone marrow, gastrointestinal tract, skin, and brain.

Symptoms include **shortness of breath**, **fever**, night sweats, weight loss, appetite loss, **fatigue**, and progressively severe **diarrhea**, stomach **pain**, **nausea and vomiting**. If the infection spreads to the brain, the patient may experience weakness, headaches, vision problems, and loss of balance.

MAC and *M. kansasii* sometimes cause lung infections in middle-aged and elderly people with chronic lung conditions. MAC, *M. kansasii*, and *M. scrofulaceum* may cause inflammation of the lymph nodes in otherwise healthy young children. *M. fortuitum* and *M. chelonae* cause skin and wound infections and abscesses after **trauma** or surgical procedures. *M. marinum* causes a nodular inflammation, usually on the arms and legs. This infection is called "swimming pool granuloma" because it is associated with swimming pools, fish tanks, and other bodies of water. *M. ulcerans* infection causes chronic skin ulcerations, usually on an arm or leg. Atypical mycobacteria infections can also occur without causing any symptoms. In such cases, a **tuberculin skin test** may be positive.

Diagnosis

The diagnosis is made from the patient's symptoms and organisms grown in culture from the site of infection. In cases of lung infection, a diagnostic workup will include a chest x ray and tests on discharges from the respiratory passages (sputum).

Treatment

These nontypical mycobacteria are not easy to treat in any patient and the problem is complicated when the person has AIDS. **Antibiotics** are not particularly effective, although rifabutin (a cousin of the anti-tuberculosis drug rifampin) and clofazimine (an anti-leprosy drug) have helped some patients. It is also possible to contain the infection to some degree by combining different drugs, including ethionamide, cycloserine, ethambutol, and streptomycin.

KEY TERMS

Culture—A test in which a sample of body fluid, such as prostatic fluid, is placed on materials specially formulated to grow microorganisms. A culture is used to learn what type of bacterium is causing infection.

Human immunodeficiency virus (HIV)—The virus that causes AIDS.

Prognosis

Because drug therapy is not sufficiently effective, the overwhelming infections caused by these mycobacteria in AIDS patients can be fatal.

Prevention

People with HIV infection can prevent or delay the onset of MAC by taking disease-preventing drugs such as rifabutin.

People with AIDS and persons with tissue damage, such as skin **wounds** or pulmonary disease, can make a number of lifestyle changes to help prevent MAC infection. Since these mycobacteria are found in most city water systems, in hospital water supplies, and in bottled water, at-risk persons should boil drinking water. Persons at risk should also avoid raw foods, especially salads, root vegetables, and unpasteurized milk or cheese. Fruits and vegetables should be peeled and rinsed thoroughly. Conventional cooking (baking, boiling or steaming) destroys mycobacteria, which are killed at 176°F (80°C).

Finally, at-risk patients should avoid contact with animals, especially birds and bird droppings. Pigeons in particular can transmit MAC.

Mycobacterium tuberculosis see **Tuberculosis**

Mycoplasma infections

Definition

Mycoplasma are the smallest of the free-living organisms. (Unlike viruses, mycoplasma can reproduce outside of living cells.) Many species within the genus *Mycoplasma* thrive as parasites in human, bird, and animal hosts. Some species can cause disease in humans.

Description

Mycoplasma are found most often on the surfaces of mucous membranes. They can cause chronic inflammatory diseases of the respiratory system, urogenital tract, and joints. The most common human illnesses caused by mycoplasma are due to infection with *M. pneumoniae,* which is responsible for 10-20% of all pneumonias. This type of **pneumonia** is also called atypical pneumonia, walking pneumonia, or community-acquired pneumonia. Infection moves easily among people in close contact because it is spread primarily when infected droplets circulate in the air (that is, become aerosolized), usually due to coughing, spitting, or sneezing.

Causes and symptoms

Atypical pneumonias can affect otherwise healthy people who have close contact with one another. Pneumonia caused by *M. pneumoniae* may start out with symptoms of an upper respiratory infection, probably a **sore throat** progressing to a dry **cough** within a few days. Gradually, **fever**, **fatigue**, muscle aches, and a cough that produces thin sputum (spit or phlegm) will emerge. Nonrespiratory symptoms may occur too: abdominal **pain**, **headache**, and **diarrhea**; about 20% of patients may have ear pain.

Another mycoplasma species, *M. hominis*, is common in the mucous membranes of the genital area (including the cervix) and can cause infection in both males and females. Its presence does not always result in symptoms.

Diagnosis

Usually, mycoplasma pneumonia will be identified after other common diagnoses are set aside. For example, a type of antibiotic known as a beta-lactam might be prescribed for a respiratory infection producing fever and cough. If symptoms do not improve in 3-5 days, the organism causing the disease is not a typical one and not susceptible to these **antibiotics**. If a Gram's stain (a common test done on sputum) does not indicate a gram-positive pathogen, the doctor will suspect a gram-negative organism, such as mycoplasma. The actual underlying organism may not be identified (it is not in almost 50% of cases of atypical pneumonia). Although it is rare, a rash may appear along with pneumonia symptoms.This should trigger suspicion of mycoplasma pneumonia, even if laboratory tests are inconclusive.

Standard x rays may reveal a patchy material that has entered the tissue; this can be evident for months. Laboratory tests include cold agglutinins, complement fixation, culture, and enzyme immunoassay. The presence of infection with *M. pneumoniae* would be indicated by a fourfold rise in *M. pneumoniae*-specific antibody in serum, during the illness or convalescence. Highly sophisticated and specific polymerase chain reaction methods (PCR) have been developed for many respiratory pathogens, including *M. pneumoniae*. They are not readily available and are very expensive.

KEY TERMS

Community-acquired—Refers to an infectious disease that is passed among individuals who have close contact with one another.

Treatment

A 2-3 week course of certain antibiotics (erythromycin, azithromycin, clarithromycin, dirithromycin, or doxycycline) is generally prescribed for atypical pneumonia. This disease is infectious for weeks, even after the patient starts antibiotics. A persistent cough may linger for 6 weeks.

Prognosis

Mycoplasma pneumonia may be involved in the onset of **asthma** in adults; other rare complications include meningoencephalitis, Guillain-Barré syndrome, mononeuritis multiplex, **myocarditis**, or **pericarditis**. This may increase the risk of acute **arrhythmias** leading to **sudden cardiac death**. However, with proper treatment and rest, recovery should be complete.

Prevention

At this time, there are no vaccines for mycoplasma infection. It is difficult to control its spread, especially in a group setting. The best measures are still the

WWW.BOOKBAZ.IR

simplest ones. Avoid exposure to people with respiratory infections whenever possible. A person who has a respiratory infection should cover the face while coughing or sneezing.

Myelodysplastic syndrome

Definition

Myelodysplastic syndrome (MDS) is a disease that is associated with decreased production of blood cells. Blood cells are produced in the bone marrow, and the blood cells of people with MDS do not mature normally. There are three major types of blood cells—red blood cells, white blood cells and platelets. Patients with MDS can have decreased production of one, two, or all three types of blood cells.

Description

Blood cells are used in the body for many different and important functions, such as carrying oxygen (red blood cells), fighting infection (white blood cells), and controlling bleeding (platelets). Blood cells are formed and stored in the bone marrow, which is the spongy tissue inside large bones. Stem cells, or immature blood cells, are stored in the bone marrow and have the ability to develop into all three types of mature blood cells. When the body needs a specific type of blood cell, the bone marrow uses its stockpile of stem cells to produce the kind of mature cells needed for that particular situation.

In patients who have MDS, blood cells fail to mature normally. In other words, the bone marrow is unable to develop a normal amount of mature blood cells, and is also not able to increase blood cell production when mature cells are needed. Sometimes, even the cells that are produced do not function normally. The marrow eventually becomes filled with the immature cells and there is not room for the normal cells to grow and develop. MDS therefore causes a shortage of functional blood cells.

Subtypes of MDS

MDS is divided into five different subtypes that are classified according to the number and appearance of blast cells in the bone marrow. It is important for doctors to know the type of MDS a patient has, because each subtype affects patients differently and requires specific treatment. The International Prognostic Scoring System (IPSS) can help the doctor to determine the best treatment for an individual patient. The subtypes are as follows:

- Refractory anemia (RA). Bone marrow with less than 5% blast cells and abnormal red blood cell blasts
- Refractory anemia with ring sideroblasts (RARS). Bone marrow with less than 5% blasts and characteristic abnormalities in red blood cells
- Refractory anemia with excess blasts (RAEB). Bone marrow with 5-20% blast cells, and higher risk of changing into acute leukemia over time
- Refractory anemia with excess blasts in transformation (RAEBT). Bone marrow with 21-30% blast cells. This form is most likely to change into acute leukemia.
- Chronic myelomonocytic leukemia (CMMoL). Marrow with 5-20% blasts and excess monocytes (a specific type of white blood cell)

Approximately 15,000 new cases are diagnosed annually in the United States. The average age at diagnosis is 70. The most common types are RA and RARS. It is rare to have MDS before age 50. MDS is slightly more common in males than in females.

Causes and symptoms

Causes

There is no clear cause for the majority of MDS cases, which is referred to as primary or *de novo* myelodysplastic syndrome. In some cases, however, MDS results from earlier cancer treatments such as radiation and/or **chemotherapy**. This type of MDS is called secondary or treatment related MDS, is often seen 3 to 7 years after the exposure, and usually occurs in younger people.

Other possible causative agents for MDS include exposure to radiation, cigarette smoke, or toxic chemicals such as benzene. Children with pre-existing

chromosomal abnormalities such as **Down syndrome** have a higher risk of developing MDS. MDS does not appear to run in families, nor can it be spread to other individuals.

Symptoms

MDS symptoms are related to the type of blood cells that the body is lacking. The earliest symptoms are usually due to anemia, which results from a shortage of mature red blood cells. Anemia causes patients to feel tired and out of breath because there is a lack of cells transporting oxygen throughout the body. MDS may also lead to a shortage of white blood cells resulting in an increased likelihood of infections. Another symptom of MDS is increased bleeding (e.g., blood in stool, nose bleeds, increased **bruises** or bleeding gums) which is due to low level of platelets. These symptoms can occur in any combination, depending on a given patient's specific subtype of MDS.

Diagnosis

Blood tests

People who have MDS usually visit their primary care doctor first, with symptoms of **fatigue**, and are then referred to a hematologist (a physician who specializes in diseases of the blood). The diagnosis of MDS requires a complete analysis of the patient's blood and bone marrow, which is done by the hematologist. A **complete blood count** (CBC) is done to determine the number of each blood cell type within the sample. Low numbers of red blood cells, white blood cells, and or platelets are signs that a patient has MDS. Numerous other medical problems such as bleeding, nutritional deficiencies, or adverse reaction to a medication can also cause low blood counts. The hematologist will investigate other causes for low blood counts before assigning a diagnosis of MDS. Blood cells in patients with MDS can also be abnormal when viewed under the microscope.

Bone marrow aspiration and biopsy

A bone marrow biopsy is required to confirm the diagnosis of MDS and determine the correct MDS subtype. This procedure involves a needle used to take a sample of marrow from inside the bone. The area of the skin where the needle is inserted is numbed and sometimes the patient is also sedated. Patients may experience some discomfort but the procedure is safe and is over fairly quickly. Marrow samples are usually taken from the back of the hip bone (iliac crest). A sample of the marrow, known as an aspirate, and a small piece of bone are both removed with the needle.

A hematologist or a pathologist (a specialist in diagnosing diseases through cell examination) will carefully examine the bone marrow sample through a microscope. Microscopic examination allows the doctor to determine the number and type of blast cells (immature cells) within the marrow in order to identify the MDS subtype. Cells from the bone marrow are also sent for cytogenetic testing, which analyzes the cells' chromosomes. Forty to seventy percent of MDS patients have abnormal bone marrow chromosomes as a result of the disease. The pattern of these abnormalities can be used to predict how a patient will respond to a particular treatment. Thus, the full set of information provided by a bone marrow biopsy and CBC will ultimately allow the doctor to recommend the most effective treatment plan.

International Prognostic Scoring System (IPSS) for MDS

Once a diagnosis of MDS is established, the doctor will calculate the IPSS score for each individual patient. The bone marrow blast percentage, chromosomal abnormalities and number of different blood types that are reduced determine the score. A score of 0 to 3.5 is assigned to each patient. Patients with lower scores have a better prognosis and usually should not undertake treatment upon initial diagnosis. Patients with a higher score have more aggressive disease and should consider more aggressive treatment.

Treatments

Supportive care

Treatment for MDS is tailored to the patient's age, general health, specific MDS subtype, and IPSS score. Treatment varies for each patient, but most treatment strategies are designed to control the symptoms of MDS. This approach is called supportive care and aims to improve the patient's quality of life.

Supportive care for the MDS patients commonly includes red blood cell transfusions to relieve symptoms related to anemia. Red cell transfusions are relatively safe and the physician will review risks and benefits with this approach. Transfusions of any type only last a certain amount of time and therefore need to be repeated at certain intervals. Platelet transfusions can also be a way to control excessive bleeding.

WWW.BOOKBAZ.IR

The doctor will decide with each individual patient when it is appropriate to give a **transfusion**. **Antibiotics** are used when needed to combat infections that can occur more frequently in patients with low white blood cell counts.

Bone marrow transplantation

Bone marrow transplantation (BMT) is a type of treatment that attempts to provide MDS patients with a cure. This strategy requires the patients to be in fairly good health and are therefore more likely to be used in younger patients. Bone marrow transplantation (BMT) has been found to be a successful treatment for MDS patients under the age of 50 (and some over 50 in good health). Following BMT, many patients are able to achieve long-term, disease-free survival. Unfortunately, most MDS patients cannot receive a traditional bone marrow transplant because of older age or because they do not have a suitable donor. Bone marrow donors are usually siblings or are obtained from the national bone marrow registry. "Mini"-bone marrow transplants use less intense chemotherapy, and are currently being tested in older patients who would otherwise not be candidates for traditional bone marrow transplants.

Chemotherapy

Chemotherapy has been used to treat some MDS patients; however, the disease often recurs after a period of time. This type of therapy uses cell-killing drugs that may also damage healthy cells in the body. Most chemotherapy drugs are associated with some side effects. For these reasons, chemotherapy is generally not used until the MDS becomes more aggressive or the patient has a high IPSS score.

Growth factors

Growth factors are natural proteins that the body normally uses to control blood production. These substances stimulate the patient's bone marrow to produce healthy blood cells. Growth factors that stimulate white cell production are G-CSF (also called neupogen or filgrastim) and GMCSF (Leukine, sargramostim). In order to increase red cell production another growth factor, erythropoietin (Procrit) is used. These growth factors are safe with few side effects and are available only in the injectable form. The physician will decide if this treatment is appropriate for an individual patient.

Alternatives

There are no alternative therapies that have been proven to successfully treat MDS. Some of the available alternative drugs can have adverse side effects and therefore a physician should be informed if they are being used.

Prognosis

The prognosis for MDS patients depends on the subtype of their disease and the IPSS score. Patients with RA, RARS or low IPSS score rarely develop leukemia and may live with disease for some years. The higher-risk patients including those with RAEB, RAEBt, CMMoL or high IPSS scores progress more rapidly, and require intensive therapy to control the disease.

Managing MDS requires frequent doctor appointments to monitor disease progression and to evaluate the response to treatment. Fortunately for many patients, advances in therapy have significantly enhanced their ability to cope with MDS. Experimental drugs and a better understanding of the disease are likely to improve the overall prognosis in the future.

Prevention

MDS is usually impossible to prevent. Being careful about daily activities and avoiding the use of aspirin-like products that thin the blood may prevent secondary complications of MDS such as bruising and bleeding. Practicing good hygiene and avoiding crowds or people with infections can sometimes prevent infections. A well balanced diet is recommended to increase overall energy.

Myelofibrosis

Definition

Myelofibrosis is a rare disease of the bone marrow in which collagen builds up fibrous scar tissue inside the marrow cavity. This is caused by the uncontrolled growth of a blood cell precursor, which results in the accumulation of scar tissue in bone marrow. Myelofibrosis goes by many names including idiopathic myelofibrosis, agnogenic myeloid metaplasia, chronic myelosclerosis, aleukemic megakaryocytic myelosis, and leukoerythroblastosis.

Description

Myelofibrosis can be associated with many other conditions including **breast cancer**, **prostate cancer**, Hodgkin's disease, non-Hodgkin's lymphoma, acute myeloid leukemia, acute lymphocytic leukemia, **hairy cell leukemia**, **multiple myeloma**, myeloproliferative diseases, **tuberculosis**, Gaucher's disease, and Paget's disease of bone. Myelofibrosis typically becomes progressively worse and can cause death.

In myelofibrosis, abnormal cells (hematopoietic stem cells) grow out of control and begin to produce both immature blood cells and excess scar (fibrous) tissue. The fibrous tissue builds up (fibrosis) primarily in the bone marrow, the place where blood cells are produced. The fibrous tissue interferes with the production of normal blood cells. The outcome of this is that the blood made by the bone marrow is of poor quality. To compensate for this, blood cell production occurs in other parts of the body (extramedullary hematopoiesis), but most notably in the spleen and liver. This causes enlargement of the spleen (splenomegaly) and the liver (hepatomegaly). Extramedullary hematopoiesis is not effective and, combined with the reduced production of blood cells by the bone marrow, a condition called anemia results.

The abnormal stem cells can spread throughout the body, settle in other organs, and form tumors that produce more abnormal blood cells and fibrous tissue. These tumors are most commonly found in the adrenals, kidneys, lymph nodes, breast, lungs, skin, bowel, thymus, thyroid, prostate, and urinary tract.

Most patients with myelofibrosis are over 50 years old; the average age at diagnosis is 65 years. However, myelofibrosis can occur at any age. Myelofibrosis occurs with equal frequency in women and men, but in children it affects girls twice as often as it does boys.

Causes and symptoms

Myelofibrosis is caused by an abnormality in a single stem cell, which causes it to grow out of control. Myelofibrosis tumors that have originated from a single cell are called monoclonal. The cause of the stem cell abnormality is unknown. Persons who were exposed to benzene or high doses of radiation have developed myelofibrosis. There may be an association between myelofibrosis and autoimmune diseases, such as **systemic lupus erythematosus** and **scleroderma**, in which the immune system treats certain molecules of the body as foreign invaders.

Symptoms usually appear slowly over a long period of time. About one quarter of all patients with myelofibrosis have no symptoms (asymptomatic). An enlarged spleen discovered at an annual medical examination may be the first clue. Symptoms of myelofibrosis include:

- fatigue
- weight loss
- paleness
- fever
- sweating
- weakness
- heart palpitations
- shortness of breath
- itchiness
- feeling full after eating a small amount of food
- stomach pain or discomfort
- pain in the left shoulder or upper left portion of the body
- unexpected bleeding
- bone pain, especially in the legs

Diagnosis

Because symptoms are similar to other diseases (mostly leukemias), myelofibrosis is not easy to diagnose. The doctor would use his or her hands to feel (palpate) for enlargement of the spleen and liver. Blood tests and urine tests would be performed. **Bone marrow aspiration and biopsy** can help make a diagnosis, but they often fail because of the fibrosis. X-ray imaging and **magnetic resonance imaging** (MRI) may be performed.

Treatment

Many asymptomatic patients, if stable, do not require treatment. There is no cure for myelofibrosis, although **bone marrow transplantation** is curative in

WWW.BOOKBAZ.IR

KEY TERMS

Anemia—Low numbers of red blood cells in the blood.

Benzene—A colorless volatile flammable toxic liquid hydrocarbon used as a solvent and as a motor fuel.

Biopsy—Surgical removal of tissue for microscopic examination.

Fibrosis—Buildup of scar tissue.

Glucocorticoid therapy—Treatment using corticoids that are anti-inflammatory and immunosuppressive.

Leukemia—Cancer of white blood cells.

Portal hypertension—Extreme pressure on the blood vessels of the liver.

Stem cell—A cell that has the ability to become many different specialized cells.

some cases. Treatment is aimed at reducing symptoms and improving quality of life.

Medications

Male hormones (androgens) can be used to treat anemia but, in women, these drugs can cause the development of male characteristics (e.g., hair growth on the face and body). Glucocorticoid therapy is also an effective treatment of anemia and can improve myelofibrosis in children. Nutrients that stimulate blood formation (hematinics), such as iron, **folic acid**, and vitamin B_{12}, may reduce anemia. Cancer-chemotherapy (usually hydroxyurea) can decrease splenomegaly and hepatomegaly, reduce symptoms of myelofibrosis, lessen anemia, and sometimes reduce bone marrow fibrosis. The bone marrow of myelofibrosis patients is often not strong enough to withstand the harsh **chemotherapy** drugs, so this treatment is not always an option. Interferon-alpha has been shown to reduce spleen size, reduce bone **pain**, and, in some cases, increase the number of blood platelets (structures involved in blood clotting).

Other treatments

In certain cases, the enlarged spleen may be removed (**splenectomy**). Conditions that warrant splenectomy include spleen pain, the need for frequent blood **transfusion**, very low levels of platelets (**thrombocytopenia**), and extreme pressure in the blood vessels of the liver (portal **hypertension**).

Radiation therapy is used to treat splenomegaly, spleen pain, bone pain, tumors in certain places such as next to the spinal cord, and fluid accumulation inside the abdomen (**ascites**). Patients who are not strong enough to undergo splenectomy are often treated with radiation therapy.

Bone marrow transplantation may be used to treat some patients with myelofibrosis. This procedure may be performed on patients who are less than 50 years old, have a poor life expectancy, and have a brother or sister with blood-type similarities.

Patients with severe anemia may require blood transfusions.

Prognosis

Similar to leukemias, myelofibrosis is progressive and often requires therapy to control the disease. Myelofibrosis can progress to acute lymphocytic leukemia or lymphoma. Although a number of factors to predict the survival time have been proposed, advanced age or severe anemia are consistently associated with a poor prognosis. The average survival rate of patients diagnosed with myelofibrosis is five years. Death is usually caused by infection, bleeding, complications of splenectomy, **heart failure**, or progression to leukemia. Spontaneous remission is rare.

Prevention

Persons who have been exposed to radiation, benzene, or radioactive thorium dioxide (a chemical used during certain diagnostic radiological procedures) are at risk for myelofibrosis.

Myelogram *see* **Myelography**

Myelography

Definition

Myelography is an x-ray examination of the spinal canal. A contrast agent is injected through a needle into the space around the spinal cord to display the spinal cord, spinal canal, and nerve roots on an x ray.

Purpose

The purpose of a myelogram is to evaluate the spinal cord and/or nerve roots for suspected compression. Pressure on these delicate structures causes **pain** or other symptoms. A myelogram is performed when precise detail about the spinal cord is needed to make a definitive diagnosis. In most cases, myelography is used after other studies, such as **magnetic resonance imaging** (MRI) or a computed tomography scan (CT scan), have not yielded enough information to be sure of the disease process. Sometimes myelography followed by CT scan is an alternative for patients who cannot have an MRI scan, because they have a pacemaker or other implanted metallic device.

A herniated or ruptured intervertebral disc, popularly known as a slipped disc, is one of the most common causes for pressure on the spinal cord or nerve roots. Discs are pads of fiber and cartilage that contain rubbery tissue. They lie between the vertebrae, or individual bones, which make up the spine. Discs act as cushions, accommodating strains, shocks, and position changes. A disc may rupture suddenly, due to injury or a sudden straining with the spine in an unnatural position. In other cases, the problem may come on gradually as a result of progressive deterioration of the discs with **aging**. The lower back is the most common area for this problem, but it sometimes occurs in the neck, and rarely in the upper back. A myelogram can help accurately locate the disc or discs involved.

Myelography may be used when a tumor is suspected. Tumors can originate in the spinal cord, or in tissues surrounding the cord. Cancers that have started in other parts of the body may spread or metastasize in the spine. It is important to precisely locate the mass causing pressure, so effective treatment can be undertaken. Patients with known cancer who develop back pain may require a myelogram for evaluation.

Other conditions that may be diagnosed using myelography include arthritic bony growths, known as spurs, narrowing of the spinal canal, called **spinal stenosis**, or malformations of the spine.

Precautions

Patients who are unable to lie still or cooperate with positioning should not have this examination. Severe congenital spinal abnormalities may make the examination technically difficult to carry out. Patients with a history of severe allergic reaction to contrast material (x-ray dye) should report this to their physician. Pretreatment with medications to minimize the risk of severe reaction may be recommended.

Description

Myelograms can be performed in a hospital x-ray department or in an outpatient **radiology** facility. The patient lies on the x-ray table on his or her stomach. The radiologist first looks at the spine under fluoroscopy, where the images appear on a monitor screen. This is done to find the best location to position the needle. The skin is cleaned, then numbed with local anesthetic. The needle is inserted. Occasionally, a small amount of cerebrospinal fluid, the clear fluid which surrounds the spinal cord and brain, may be withdrawn through the needle and sent for laboratory studies. Then contrast material is injected. The contrast material (dye) is a liquid that shows up on x rays.

The x-ray table is tilted slowly. This allows the contrast material to reach different levels in the spinal canal. The flow is observed under fluoroscopy, then x rays are taken with the table tilted at various angles. A footrest and shoulder straps or supports will keep the patient from sliding.

In many instances, a CT scan of the spine will be performed immediately after a myelogram, while the contrast material is still in the spinal canal. This helps outline internal structures most clearly.

A myelogram takes approximately 30–60 minutes. A CT scan adds about another hour to the examination. If the procedure is done as an outpatient exam, some facilities prefer the patient to stay in a recovery area for up to four hours.

Preparation

Patients should be well hydrated at the time of a myelogram. Increasing fluids the day before the study is usually recommended. All food and fluid intake should be stopped approximately four hours before the myelogram.

Certain medications may need to be stopped for one to two days before myelography is performed. These include some antipsychotics, antidepressants, blood thinners, and diabetic medications. Patients should

WWW.BOOKBAZ.IR

consult with their physician and/or the facility where the study is to be done.

Patients who smoke may be asked to stop the day before the test. This helps decrease the chance of nausea or headaches after the myelogram. Immediately before the examination, patients should empty their bowels and bladder.

Aftercare

After the examination is completed, the patient usually rests for several hours, with the head elevated. Extra fluids are encouraged, to help eliminate the contrast material and prevent headaches. A regular diet and routine medications may be resumed. Strenuous physical activity, especially any which involve bending over, may be discouraged for one or two days. The doctor should be notified if a **fever**, excessive **nausea and vomiting**, severe **headache**, or stiff neck develops.

Risks

Headache is a common complication of myelography. It may begin several hours to several days after the examination. The cause is thought to be changes in cerebrospinal fluid pressure, not a reaction to the dye. The headache may be mild and easily alleviated with rest and increased fluids. Sometimes, nonprescription medicine are recommended. In some instances, the headache may be more severe and require stronger medication or other measures for relief. Many factors influence whether the patient develops this problem. These include the type of needle used and the age and sex of the patient. Patients with a history of chronic or recurrent headache are more likely to develop a headache after a myelogram.

The chance of reaction to the contrast material is a very small, but potentially significant risk with myelography. It is estimated that only 5-10% of patients experience any effect from contrast exposure. The vast majority of reactions are mild, such as sneezing, nausea, or **anxiety**. These usually resolve by themselves. A moderate reaction, like **wheezing** or **hives**, may be treated with medication, but is not considered life threatening. Severe reactions, such as heart or **respiratory failure**, happen very infrequently. These require emergency medical treatment.

Rare complications of myelography include injury to the nerve roots from the needle, or from bleeding into the spaces around the roots. Inflammation of the delicate covering of the spinal cord, called arachnoiditis, or infections, can also occur. Seizures are another very uncommon complication reported after myelography.

KEY TERMS

Contrast agent—Also called a contrast medium, usually a barium or iodine dye that is injected into the area under investigation. The dye makes the interior body parts more visible on an x-ray film.

Results

A normal myelogram would show a spinal canal of normal width, with no areas of constriction or obstruction.

Abnormal results

A myelogram may reveal a **herniated disk**, tumor, bone spurs, or narrowing of the spinal canal (spinal stenosis).

Myeloma *see* **Multiple myeloma**

Myers-Briggs type indicator

Definition

The Myers-Briggs Type Indicator (MBTI) is a widely used personality inventory, or test, employed in vocational, educational, and **psychotherapy** settings to evaluate personality type in persons age 14 and older.

Purpose

In an educational setting, the MBTI may be performed to assess student learning style. Career counselors use the test to help others determine what occupational field they might be best suited for, and it is also used in organizational settings to assess management skills and facilitate teamwork and

problem-solving, including communication difficulties. Because the MBTI is also a tool for self-discovery, mental health professionals may administer the test in counseling sessions to provide their patients with insight into their behavior.

As of the early 2000s, the MBTI was being used in the mental health field to assess vulnerability to **anxiety disorders** and depression. Preliminary results indicate that some of the 16 types are more susceptible to **mood disorders** than others. ISFPs, for example, are overrepresented among patients in treatment for unipolar depression, while the four ST types appear to be more vulnerable to **anxiety** states.

Precautions

The MBTI should be administered, scored, and interpreted only by a professional trained in its use. Cultural and language differences in the test subject may affect performance and may result in inaccurate test results. The test administrator should be informed before testing begins if the test taker is not fluent in English and/or he has a unique cultural background.

Description

In 2000, an estimated two million people took the MBTI, making it the most frequently used personality inventory available. The test was first introduced in 1942, the work of a mother and daughter, Katharine Cook Briggs and Isabel Briggs Myers. There are now several different versions of the test available. Form M, which contains 93 items, is the most commonly used.

The Myers-Briggs inventory is based on Carl Jung's theory of types, outlined in his 1921 work *Psychological Types*. Jung's theory holds that human beings are either *introverts* or *extraverts*, and their behavior follows from these inborn psychological types. He also believed that people take in and process information different ways, based on their personality traits.

The Myers-Briggs evaluates personality type and preference based on the four Jungian psychological types:

- extraversion (E) or introversion (I)
- sensing (S) or intuition (N)
- thinking (T) or feeling (F)
- judging (J) or perceiving (P)

KEY TERMS

Multitasking—Performing multiple duties or taking on multiple responsibilities and roles simultaneously.

Vocational—Relating to an occupation, career, or job.

Preparation

Prior to the administration of the MBTI, the test subject should be fully informed about the nature of the test and its intended use. He or she should also receive standardized instructions for taking the test and any information on the confidentiality of the results.

Results

Myers-Briggs results are reported as a four-letter personality type (e.g., ESTP, ISFJ). Each letter corresponds to an individual's preference in each of the four pairs of personality indicators (i.e., E or I, S or N, T or F, and J or P). There are a total of sixteen possible combinations of personality types on the MBTI.

Letter One: E or I

Extraverts focus more on people and subjects in the outside world, introverts on internal thoughts and ideas.

Letter Two: S or N

Sensing dominant personalities prefer to perceive objects through sight, sound, taste, touch, and smell, while intuition dominant types look to past experience and are more abstract in their thinking.

Letter Three: T or F

The third subtype is a measure of how people use judgment. Thinking types use logic to judge the world, while feeling types tend to view subjects on the basis of what emotions they elicit.

Letter Four: J or P

Everyone judges and perceives, but those who are judging dominant are said to be more methodical and results-oriented, while perceiving dominant personalities are good at multitasking and are flexible.

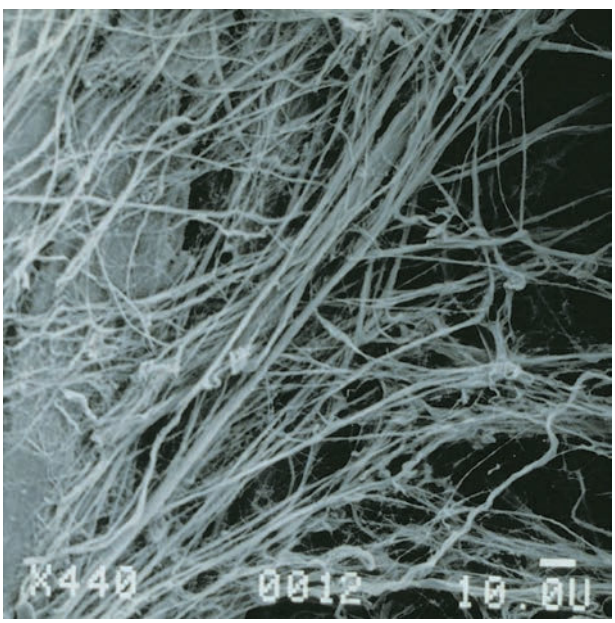
Myocardial biopsy

Definition

Myocardial biopsy is a procedure wherein a small portion of tissue is removed from the heart muscle for testing. This test is also known as endomyocardial biopsy.



Once the catheter is threaded up into the heart, the surgeon will take several small samples of muscle for laboratory analysis. *(Custom Medical Stock Photo, Inc.)*

Purpose

The main reason for a biopsy is to secure tissue samples that will be useful in the diagnosis, treatment, and care of heart muscle disorders. The test is also used to detect rejection after a **heart transplantation** procedure.

Precautions

This procedure is not used when the patient is taking blood-thinning medication (anticoagulant therapy). It should not be done when the patient has leukemia and **aplastic anemia** or if there is a blood clot on the interior wall of the heart.

Description

A long, flexible tube, called a catheter, is inserted into a vein and threaded up into the heart. The doctor can guide the catheter by watching its movement on a TV monitor showing an x-ray image of the area. The tip of the catheter is fitted with tiny jaws that the doctor can open and close. Once the catheter is in place, the doctor will take several small snips of muscle for microscopic examination.

Preparation

Preparation for myocardial biopsy is quite extensive. The patient will be asked not to eat for several hours before the procedure. A technician will shave the hair from the area of the incision and will also insert an intravenous line in the arm. The patient will be given a sedative to relax but will not be fully anesthetized. The patient will be connected to an electrocardiograph (ECG) to monitor the heart, and a blood-pressure cuff will be placed. Finally, the patient will be covered with sterile drapes, so that the area of the biopsy is kept free of germs. The cardiologist will numb the area where the catheter will be inserted.

Aftercare

At the end of the biopsy, the catheter will be removed and pressure will be applied at the site where it entered the blood vessel in order to encourage healing. The patient will then be taken to the recovery room. It is advisable to remain flat and not to move about for 6–8 hours. After that time, most people begin walking around. Swelling and bruising at the puncture site are common and usually go away without need for further attention.

KEY TERMS

Anticoagulant—Medication that thins the blood and slows clot formation.

Aplastic anemia—A greatly decreased production of all of the formed elements of the blood caused by a failure of the cell-generating capacity of the bone marrow.

Electrocardiography—A test that uses electrodes attached to the chest with an adhesive gel to transmit the electrical impulses of the heart muscle to a recording device.

Leukemia—A disease characterized by an increasing number of abnormal cells in the blood.

Risks

The risks involved with myocardial biopsy are small because the patient is monitored closely and attended by well-trained staff. Racing of the heart (**palpitations**) and quivering of the heart muscles (**atrial fibrillation**) are both possible during the procedure.

Myocardial infarction *see* **Heart attack**

Myocardial resection

Definition

Myocardial resection is a surgical procedure in which a portion of the heart muscle is removed.

Purpose

Myocardial resection is done to improve the stability of the heart function or rhythm. Also known as endocardial resection, this open-heart surgery is done to destroy or remove damaged areas, because these areas can generate life-threatening heart rhythms. Conditions resulting in abnormal heart rhythms caused by re-entry pathways or aberrant cells are corrected with this treatment.

Areas of the heart involved in a myocardial infarction (**heart attack**) change in contractility and function, becoming scar tissue that thins and hinders its ability to contract. Removing this diseased area can improve myocardial contractility, thus reversing the severity of chronic **heart failure**. This procedure has shown promise for patients with chronic heart failure and is intended to improve cardiac output and quality of life.

Demographics

Patients are not limited by age, race, or sex when being evaluated for myocardial resection surgery. Patients who experience **angina**, **congestive heart failure**, **arrhythmias**, and **pulmonary edema** (fluid in the lungs) are candidates for this procedure. Contraindications (conditions in which the surgery is not recommended) include right heart failure, high pressure in the blood coming from the left ventricle (lower chamber), and **pulmonary hypertension** (high blood pressure in the circulation around the lungs).

Description

After the patient receives a general anesthetic, an incision will be made in the chest to expose the heart. Cardiopulmonary bypass (to a heart-lung machine) will be instituted, because this procedure requires direct visualization of the heart muscle. Since this is a true open-heart procedure, the heart will be unable to pump blood during the surgery.

Arrhythmias

When the exact source of the abnormal rhythm is identified, it is removed. If there are areas around the source that may contribute to the problem, they can be frozen with a special probe. The amount of tissue removed is so small, usually only 2–3 millimeters (mm), that there is no damage to the structure of the heart.

Ventricular reconstruction

A weakened myocardium (heart muscle) causes the heart to remodel and become less efficient at pumping blood. The goal is to remove the damaged region of the free wall of the left ventricle along with any involved septum. The heart is then reconstructed to provide a more elliptical structure that pumps blood more efficiently. In some instances, a Dacron graft is used to replace the removed myocardium to aid in the reconstruction.

WWW.BOOKBAZ.IR

KEY TERMS

Arrhythmia—An abnormal heart rhythm. Examples are a slow, fast, or irregular heart rate.

Cardiac catheterization—A diagnostic procedure in which a thin tube is inserted into an artery or vein and guided to the heart using x rays. The function of the heart and blood vessels can be evaluated using this technique.

Dacron graft—A synthetic material used in the repair or replacement of blood vessels.

Ejection fraction—The amount of blood pumped out at each heartbeat, usually expressed as a percentage.

Implantable cardioverter-defibrillator—A device placed in the body to deliver an electrical shock to the heart in response to a serious abnormal rhythm.

Infarction—Tissue death resulting from a lack of oxygen to the area.

Intra-aortic balloon pump—A temporary device inserted into the femoral artery and guided upward to the aorta. The small balloon helps strengthen heart contractions by maintaining improved blood pressure.

Radiofrequency ablation—A procedure in which a catheter is guided to an area of the heart where abnormal heart rhythms originate. The cells in that area are killed using a mild radiofrequency energy to restore normal heart contractions.

Wolff-Parkinson-White syndrome—An abnormal rapid heart rhythm, due to an extra pathway for the electrical impulses to travel from the atria to the ventricles.

Diagnosis

Diagnosis of arrhythmias begins with a Holter monitor that can identify the type of arrhythmia. This is followed by a **cardiac catheterization** to find the aberrant cells generating the arrhythmia. The patient is then recommended for open-heart surgery to remove the cells generating the arrhythmia.

Diagnosis of chronic heart failure is demonstrated by a cardiac catheterization or nuclear medicine study. During cardiac catheterization, the patient's cardiac function will be measured by cardiac output, ejection fraction, and cardiovascular pressures. A nuclear medicine study can demonstrate areas of the myocardium that are damaged. Muscle that is akinetic (does not move) will be identified. This information allows the surgeon to identify candidates for myocardial resection.

Preparation

Electrophysiologists, cardiac surgeons, and cardiologists specially trained in cardiac electrical signaling and ventricular reconstruction have undergone specific training in these procedures. The number of patients suitable for these procedures is limited, so experienced physicians should be sought to provide medical treatment.

Myocardial resection is major surgery and should be the treatment of choice only after medications have failed and the use of an implantable cardioverter-defibrillator (a device that delivers electrical shocks to control heart rhythm) has been ruled out along with medical therapy.

Prior to surgery, the physician will explain the procedure and order blood tests of the formed blood elements and electrolytes.

Aftercare

Immediately after surgery, the patient will be transferred to the intensive care unit for further cardiac monitoring. Any medications administered to improve cardiac performance will be reduced as necessary to allow the heart's natural function to return. The patient will be able to leave the hospital within five days, assuming there are no complications. Complications may includesurgical bleeding, infection, or the need insert an intra-aortic balloon pump ventricular assist device.

Risks

The risks of myocardial resection are based in large part on the patient's underlying heart condition and, therefore, vary greatly. The procedure involves opening the heart, so the person is at risk for the complications associated with major heart surgery, such as **stroke**, **shock**, infection, and hemorrhage. Since the amount of myocardium to remove is not precise, a patient may demonstrate little benefit in cardiac performance. If not enough or too much tissue is removed, the patient will continue to have heart problems.

General **anesthesia** with inhalation gases should be avoided as they can promote arrhythmias. Therefore, anesthesia should be limited to intravenous medications.

Results

Following this procedure, up to 90% of patients are arrhythmia-free at the end of one year, and in one

study, 80% of patients had remained event free after five years.

Morbidity and mortality rates

Cardiopulmonary bypass has an associated risk of complications separate from myocardial resection, with patients over 70 years of age being prone to increased morbidity and mortality.

Alternatives

If myocardial resection is being performed to prevent arrhythmia generation, new techniques allow for minimally invasive procedures to be performed, including radiofrequency ablation performed in an electrophysiology laboratory with mild **sedation** instead of general anesthetic.

If ventricular restoration is contraindicated, medical treatment will be continued. Mechanical circulatory assist with a ventricular assist device may be a suitable option. Heart transplant and total artificial heart implantation should also be explored as alternative therapies.

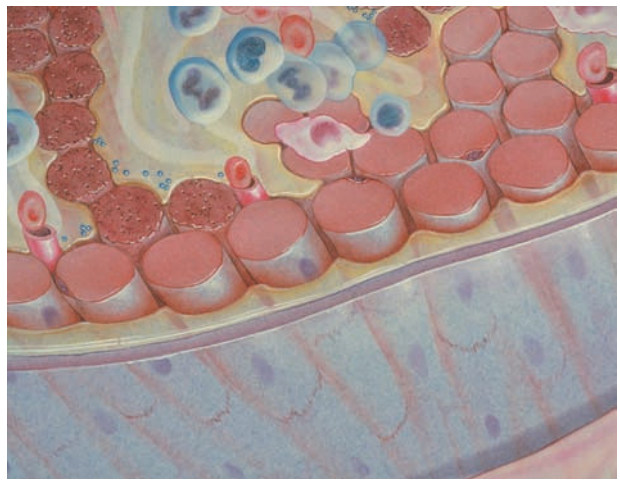
Myocarditis

Definition

Myocarditis is an inflammatory disease of the heart muscle (myocardium) that can result from a variety of causes. While most cases are produced by a viral infection, an inflammation of the heart muscle may also be instigated by toxins, drugs, and hypersensitive immune reactions. Myocarditis is a rare but serious condition that affects both males and females of any age.



This illustration depicts the inflammation of the myocarditis, the middle muscular layer of the heart wall. *(Custom Medical Stock Photo, Inc.)*

Description

Most cases of myocarditis in the United States originate from a virus, and the disease may remain undiagnosed by doctors due to its general lack of initial symptoms. The disease may also present itself as an acute, catastrophic illness that requires immediate treatment. Although the inflammation or degeneration of the heart muscle that myocarditis causes may be fatal, this disease often goes undetected. It may also disguise itself as ischemic, valvular, or hypertensive **heart disease**.

An inflammation of the heart muscle may occur as an isolated disorder or be the dominating feature of a systemic disease (one that affects the whole body, like **systemic lupus erythematosus**).

Causes and symptoms

While there are several contributing factors that may lead to myocarditis, the primary cause is viral. Myocarditis usually results from the Coxsackie B virus, and may also result from **measles**, **influenza**, chicken pox, hepatitis virus, or the adenovirus in children. If an acute onset of severe myocarditis occurs, a patient may display the following symptoms:

- Rhythm disturbances of the heart
- Rapid heartbeat (Ventricular tachycardia)
- Left or right ventricular enlargement
- Shortness of breath (Dyspnea)

WWW.BOOKBAZ.IR

KEY TERMS

Adenovirus—One type of virus that can cause upper respiratory tract infections.

Angiography—A procedure that uses x ray after injecting a radiopaque substance to examine the blood vessels and lymphatics.

Arrhythmia—An irregular heartbeat or action.

Cardiac catheterization—A diagnostic procedure that gives a comprehensive examination of how the heart and its blood vessels function; performed by inserting one or more catheters through a peripheral blood vessel in the arm or leg.

Coxsackie B virus—A mild virus belonging to a group of viruses (coxsackievirus) that may produce a variety of illnesses, including myocarditis.

Echocardiography—A noninvasive diagnostic procedure that uses ultrasound to examine internal cardiac structures.

Electrocardiogram—A record of the electrical activity of the heart, with each wave being labeled as P, Q, R, S, and T waves. Often used in the diagnosis of cases of abnormal cardiac rhythm and myocardial damage.

Hypertensive heart disease—High blood pressure resulting in a disease of the heart.

Ischemic heart disease—Insufficient blood supply to the heart muscle (myocardium).

Valvular heart disease—A disease of any one of the four valves that controls blood flow into, through, and out of the heart.

Ventricular tachycardia—An abnormally rapid heartbeat. It includes a series of at least three beats arising from a ventricular area at a rate of more than 100 beats per minute, usually ranging from 150-200 beats per minute.

- Pulmonary edema (the accumulation of fluid in the lungs due to left-sided heart failure)
- Swollen legs

Additional causes of myocarditis include:

- Bacterial infections, such as tetanus, gonorrhea, or tuberculosis
- Parasite infections, such as Chagas' disease (which is caused by an insect-borne protozoan most commonly seen in Central and South America)
- Rheumatic fever
- Surgery on the heart
- Radiation therapy for cancer that is localized in the chest, such as breast or lung cancer
- Certain medications

Research has shown that illegal drugs and toxic substances may also produce acute or chronic injury to the myocardium. These studies also indicate an increase in the incidence of toxic results from the use of cocaine. This illegal drug causes coronary artery spasm, myocardial infarction (**heart attack**), and **arrhythmias**, as well as myocarditis.

Further studies conducted in 1996 indicated that **malnutrition** encourages the Coxsackie B virus to flourish, leading to the potential development of myocarditis. Human **immunodeficiency** virus (HIV) is also now recognized as a cause of myocarditis, though its prevalence is not known.

Symptoms of myocarditis may start as **fatigue**, **shortness of breath**, **fever**, and aching of the joints, all characteristic of a flu-like illness. In contrast to this type of mild appearance, myocarditis may also appear suddenly in the form of **heart failure**, or **sudden cardiac death** without any prior symptoms. If an inflammation of the heart muscle leads to **congestive heart failure**, symptoms such as swollen feet and ankles, distended neck veins, a rapid heartbeat, and difficulty breathing while reclining may all appear.

Diagnosis

The best way to diagnose myocarditis may be through a person's observation of his or her own symptoms, followed by a thorough medical history and physical exam conducted by a doctor. Further tests usually include laboratory blood studies and **echocardiography**. An electrocardiogram (ECG) is also routinely used due to its ability to detect a mild case of the disease. **Cardiac catheterization** and **angiography** are additional diagnostic tests used to determine the presence of myocarditis, or to rule out other possible heart diseases that may lead to heart failure.

Another measure used to diagnosis myocarditis is the endomyocardial biopsy procedure. This invasive catheterization procedure examines a biopsied, or "snipped," piece of the endocardium (the lining

membrane of the inner surface of the heart). The tissue sample is examined to verify the presence of the disease, as well as to try to determine the infective cause. An approach used only with a patient's consent, this procedure may also confirm acute myocarditis, allowing close monitoring of potential congestive heart failure.

Treatment

While myocarditis is a serious condition, there is no medical treatment necessary if it results from a general viral infection. The only steps to recovery include rest and avoidance of physical exertion. Adequate rest becomes more important to recovery if the case is severe myocarditis with signs of dilated **cardiomyopathy** (disease of the heart muscles). In this case, medical treatment for congestive heart failure may include the following medications: angiotensin converting enzyme (ACE) inhibitors, **diuretics** to reduce fluid retention, digitalis to stimulate a stronger heartbeat, and low-dose beta-blockers.

If myocarditis is caused by a bacterial infection, the disease is treated with **antibiotics** to fight the infection. If severe rhythm disturbances are involved, cardiac assist devices, an "artificial heart," or **heart transplantation** may be the only option for complete recovery.

Prognosis

The outlook for a diagnosed case of myocarditis caused by a viral infection is excellent, with many cases healing themselves spontaneously. Severe or acute myocarditis may be controlled with medication to prevent heart failure. Because this disease may be mild or may be extreme and cause serious arrhythmias, the prognosis varies. Cases of myocarditis may vary from complete healing (with or without significant scarring), to severe congestive heart failure leading to death or requiring a heart transplant.

Inflammation of the myocardium may also cause acute **pericarditis** (inflammation of the outer lining of the heart). Due to the potential effects of the disease, including sudden death, it is imperative that proper medical attention is obtained.

Prevention

Although myocarditis is an unpredictable disease, the following measures may help prevent its onset. Individuals should:

- take extra measures to avoid infections and obtain appropriate treatment for infections.
- limit alcohol consumption to no more than one or two drinks a day, if any.
- maintain current immunizations against diphtheria, tetanus, measles, rubella, and polio.
- avoid anything that may cause the abnormal heart to work too hard, including salt and vigorous exercise.

Beth A. Kapes

Myoglobin test

Definition

Myoglobin is a protein found in muscle. Myoglobin tests are done to evaluate a person who has symptoms of a **heart attack** (myocardial infarction) or other muscle damage.

Purpose

Myoglobin holds oxygen inside heart and skeletal muscle (muscles that attach to and move bones). It is continually released into the blood in small amounts due to normal turnover of muscle cells. Kidneys discard the myoglobin into urine.

When muscle is damaged, as in a heart attack, larger amounts of myoglobin are released and blood levels rise rapidly. Myoglobin is one of the first tests done to determine if a person with chest **pain** is having a heart attack, as it may be one of the first blood tests to become abnormal.

Damage or injury to skeletal muscle also causes myoglobin to be released into the blood.

Description

Heart attack must be diagnosed quickly. Medications to prevent heart damage are effective only within a limited number of hours. Yet, because of their risk for excessive bleeding, these medications are given only after a diagnosis of heart attack is made.

WWW.BOOKBAZ.IR

KEY TERMS

Cardiac marker—A substance in the blood that rises following a heart attack.

Diagnostic window—A cardiac marker's timeline for rising, peaking, and returning to normal after a heart attack.

Myoglobin—A protein that holds oxygen in heart and skeletal muscle. It rises after damage to either of these muscle types.

Myoglobin is one of several cardiac markers used to make the diagnosis. Cardiac markers are substances in blood whose levels rise in the hours following a heart attack. Increased levels help diagnose a heart attack; persistent normal levels rule it out.

Each cardiac marker rises, peaks, and returns to a normal level according to its own timeline, or diagnostic window. Myoglobin is useful because it has the earliest diagnostic window. It is the first marker to rise after chest pain begins. Myoglobin levels rise within two to three hours, and sometimes as early as 30 minutes. They peak after six to nine hours. The levels return to normal within 24–36 hours.

Although a rise in myoglobin supports a diagnosis of heart attack, it is not conclusive. Simultaneous skeletal muscle damage could also cause the increase. Myoglobin rules out, rather than proves, a diagnosis in the following way. If myoglobin levels have not risen after more than five hours, a heart attack in unlikely. Normal levels in the first two to three hours do not rule out an infarction.

The myoglobin test is sometimes repeated every one to two hours to watch for the rise and peak. Results are available within 30 minutes.

Myoglobin in large amounts is toxic to the kidney. When a person has high amounts of myoglobin in the blood, kidney function must be monitored.

Preparation

This test requires 5 mL of blood. Collection of the sample takes only a few minutes. A urine myoglobin test requires 1 mL of urine collected into a urine collection cup.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Results

Normal results vary based on the laboratory and method used.

Abnormal results

Myoglobin levels and levels of other cardiac markers are usually considered before finally confirming a diagnosis of heart attack. A level that has doubled after one to two hours, even if the level is still in the normal range, indicates a significant rise that may be due to heart attack.

Increased levels are also found with skeletal muscle damage or disease, such as an injury, **muscular dystrophy**, or **polymyositis**. Myoglobin levels also rise during renal failure because kidneys lose their ability to clear myoglobin from blood.

Myomas *see* **Uterine fibroids**

Myomectomy

Definition

Myomectomy is the removal of fibroids (noncancerous tumors) from the wall of the uterus. Myomectomy is the preferred treatment for symptomatic fibroids in women who want to keep their uterus. Larger fibroids must be removed with an abdominal incision, but small fibroids can be taken out using **laparoscopy** or **hysteroscopy**.

Purpose

A myomectomy can remove **uterine fibroids** that are causing symptoms. It is an alternative to surgical removal of the whole uterus (**hysterectomy**). The procedure can relieve fibroid-induced menstrual symptoms that have not responded to medication. Myomectomy also may be an effective treatment for **infertility** caused by the presence of fibroids.

Precautions

There is a risk that removal of the fibroids may lead to such severe bleeding that the uterus itself will have to be removed. Because of the risk of blood loss during a myomectomy, patients may want to consider banking their own blood before surgery.

Description

Usually, fibroids are buried in the outer wall of the uterus and abdominal surgery is required. If they are on the inner wall of the uterus, uterine fibroids can be removed using hysteroscopy. If they are on a stalk (pedunculated) on the outer surface of the uterus, laparoscopy can be performed.

Removing fibroids through abdominal surgery is a more difficult and slightly more risky operation than a hysterectomy. This is because the uterus bleeds from the sites where the fibroids were, and it may be difficult or impossible to stop the bleeding. This surgery is usually performed under general **anesthesia**, although some patients may be given a spinal or epidural anesthesia.

The incision may be horizontal (the "bikini" incision) or a vertical incision from the navel downward. After separating the muscle layers underneath the skin, the surgeon makes an opening in the abdominal wall. Next, the surgeon makes an incision over each fibroid, grasping and pulling out each growth.

Every opening in the uterine wall is then stitched with sutures. The uterus must be meticulously repaired in order to eliminate potential sites of bleeding or infection. Then, the surgeon sutures the abdominal wall and muscle layers above it with absorbable stitches, and closes the skin with clips or nonabsorbable stitches.

When appropriate, a laparoscopic myomectomy may be performed. In this procedure, the surgeon removes fibroids with the help of a viewing tube (laparoscope) inserted into the pelvic cavity through an incision in the navel. The fibroids are removed through a tiny incision under the navel that is much smaller than the 4 or 5 inch opening required for a standard myomectomy.

If the fibroids are small and located on the inner surface of the uterus, they can be removed with a thin telescope-like device called a hysteroscope. The hysteroscope is inserted into the vagina through the cervix and into the uterus. This procedure does not require any abdominal incision, so hospitalization is shorter.

KEY TERMS

Epidural anesthesia—A method of pain relief for surgery in which local anesthetic is injected into the epidural space in the middle and lower back.

Preparation

Surgeons often recommend hormone treatment with a drug called leuprolide (Lupron) two to six months before surgery in order to shrink the fibroids. This makes the fibroids easier to remove. In addition, Lupron stops menstruation, so women who are anemic have an opportunity to build up their blood count. While the drug treatment may reduce the risk of excess blood loss during surgery, there is a small risk that temporarily smaller fibroids might be missed during myomectomy, only to enlarge later after the surgery is completed.

Aftercare

Patients may need four to six weeks of recovery following a standard myomectomy before they can return to normal activities. Women who have had laparoscopic or hysteroscopic myomectomies, however, can leave the hospital the day after surgery and usually recovery completely within two to three days to one to three weeks.

Risks

The risks of a myomectomy performed by a skilled surgeon are about the same as hysterectomy (one of the most common and safest surgeries). Removing multiple fibroids is more difficult and slightly more risky.

Possible complications include:

- Infection.
- Blood loss.
- The wall of the uterus may be weakened if the removal of a large fibroid leaves a wound that extends the complete thickness of the wall. Special precautions may be needed in future pregnancies. For example, the delivery may need to be performed surgically (Caesarean section).
- Adverse reactions to anesthesia.
- Internal scarring (and possible infertility).

Since fibroids tend to appear and grow as a woman ages (until **menopause**), it is possible that new fibroids will appear after myomectomy.

Myopathies

Definition

Myopathies are diseases of skeletal muscle that are not caused by nerve disorders. These diseases cause the skeletal or voluntary muscles to become weak or wasted.

Description

There are many different types of myopathies, some of which are inherited, some inflammatory, and some caused by endocrine problems. Myopathies are rare and not usually fatal. Typically, effects are mild, largely causing muscle weakness and movement problems, and many are transitory. Only rarely do patients become dependent on a wheelchair. However, **muscular dystrophy** (which is technically a form of myopathy) is far more severe. Some types of this disease are fatal in early adulthood.

Demographics

Myopathies are not common, with a worldwide rate of 5–10 individuals per 100,000. Cases occur more often in women.

Causes and symptoms

Myopathies are usually degenerative, but they are sometimes caused by drug side effects, chemical **poisoning**, or a chronic disorder of the immune system.

Genetic myopathies

Among their many functions, genes are responsible for overseeing the production of proteins important in maintaining healthy cells. Muscle cells produce thousands of proteins. With each of the inherited myopathies, a genetic defect is linked to a lack of, or problem with, one of the proteins needed for normal muscle cell function.

There are several different kinds of myopathy caused by defective genes:

- central core disease
- centronuclear (myotubular) myopathy
- myotonia congenita
- nemaline myopathy
- paramyotonia congenita
- periodic paralysis (hypokalemic and hyperkalemic forms)
- mitochondrial myopathies

Most of these genetic myopathies are dominant, which means that a child needs to inherit only one copy of the defective gene from one parent in order to have the disease. The parent with the defective gene also has the disorder, and each of this parent's children has a 50% chance of also inheriting the disease. Male and female children are equally at risk.

However, one form of myotonia congenita and some forms of nemaline myopathy must be inherited from both parents, who carry a recessive defective gene and have no symptoms of the disease. Each child of such parents has a 25% chance of inheriting both genes and showing signs of the disease and a 50% chance of inheriting one defective gene from only one parent. If the child inherited just one defective gene, the child would be a carrier but would not show signs of the disease.

A few forms of centronuclear myopathy develop primarily in males. Females who inherit the defective gene are usually carriers without symptoms, like their mothers, but they can pass on the disease to their sons. Mitochondrial myopathies are inherited through the mother, since sperm do not contain mitochondria. (Mitochondria play a key role in energy production in the body's cells.)

The major symptoms associated with the genetic myopathies are:

- central core disease: mild weakness of voluntary muscles, especially in the hips and legs; hip displacement; delays in reaching developmental motor milestones; problems with running, jumping, and climbing stairs developing in childhood
- centronuclear myopathy: weakness of voluntary muscles, including those on the face, arms, legs, and trunk; drooping upper eyelids; facial weakness; foot drop; affected muscles almost always lacking reflexes
- myotonia congenita: voluntary muscles of the arms, legs, and face are stiff or slow to relax after contracting (myotonia); stiffness triggered by fatigue, stress, cold, or long rest periods, such as a night's sleep; stiffness relieved by repeated movement of the affected muscles

- nemaline myopathy: moderate weakness of voluntary muscles in the arms, legs, and trunk; mild weakness of facial muscles; delays in reaching developmental motor milestones; decreased or absent reflexes in affected muscles; long, narrow face; high-arched palate; jaw projecting beyond upper part of the face
- paramyotonia congenita: stiffness (myotonia) of voluntary muscles in the face, hands, and forearms; attacks spontaneous or triggered by cold temperatures; stiffness made worse by repeated movement; episodes of stiffness lasting longer than those seen in myotonia congenita
- periodic paralysis: attacks of temporary muscle weakness (muscles working normally between attacks); in the hypokalemic (low calcium) form, attacks triggered by vigorous exercise, meals high in carbohydrates, insulin, stress, alcohol, infection, pregnancy; in the hyperkalemic (normal/high calcium) form, attacks triggered by vigorous exercise, stress, pregnancy, missing a meal, steroid drugs, high potassium intake
- mitochondrial myopathies: symptoms vary quite widely with the form of the disease and may include progressive weakness of the eye muscles (ocular myopathy), weakness of the arms and legs, or multisystem problems primarily involving the brain and muscles

Endocrine-related myopathies

In some cases, myopathies can be caused by a malfunctioning gland (or glands), which produces either too much or too little of the chemical messengers called hormones. Hormones are carried by the blood and one of their many functions is to regulate muscle activity. Problems in producing hormones can lead to muscle weakness.

Hyperthyroid myopathy and hypothyroid myopathy affect different muscles in different ways. Hyperthyroid myopathy occurs when the thyroid gland produces too much thyroxine, leading to muscle weakness, some muscle wasting in hips and shoulders, and, sometimes, problems with eye muscles. The hypothyroid type occurs when too little hormone is produced, leading to stiffness, cramps, and weakness of arm and leg muscles.

Inflammatory myopathies

Some myopathies are inflammatory, leading to inflamed, weakened muscles. Inflammation is a protective response of injured tissues characterized by redness, increased heat, swelling, and/or **pain** in the affected area. Examples of this type include **polymyositis**, **dermatomyositis**, and **myositis** ossificans.

Dermatomyositis is a disease of the connective tissue that also involves weak, tender, inflamed muscles. In fact, muscle tissue loss may be so severe that the person may be unable to walk. Skin inflammation is also present. The cause is unknown, but viral infection and **antibiotics** are associated with the condition. In some cases, dermatomyositis is associated with rheumatologic disease or cancer. Polymyositis involves inflammation of many muscles usually accompanied by deformity, swelling, sleeplessness, pain, sweating, and tension. It, too, may be associated with cancer. Myositis ossificans is a rare inherited disease in which muscle tissue is replaced by bone, beginning in childhood.

Muscular dystrophy

While considered to be a separate group of diseases, the muscular dystrophies also technically involve muscle wasting and can be described as myopathies. These relatively rare diseases appear during childhood and adolescence and are caused by muscle destruction or degeneration. They are a group of genetic disorders caused by problems in the production of key proteins.

The forms of muscular dystrophy (MD) differ according to the way they are inherited, the age of onset, the muscles they affect, and how fast they progress. The most common type is Duchenne MD, affecting one or two in every 10,000 boys. Other types of MD are Becker's, **myotonic dystrophy**, limb-girdle MD, and facioscapulohumeral MD.

Diagnosis

Early diagnosis of myopathy is important so that the best possible care can be provided as soon as possible. An experienced physician can diagnose a myopathy by evaluating a person's medical history and by performing a thorough physical exam. Diagnostic tests can help differentiate between the different types of myopathy, as well as between myopathy and other neuromuscular disorders. If the doctor suspects a genetic myopathy, a thorough family history is also taken.

Diagnostic tests the doctor may order include:

- measurements of potassium in the blood
- muscle biopsy
- electromyogram (EMG)

WWW.BOOKBAZ.IR

KEY TERMS

Electromyogram (EMG)—A diagnostic test that records the electrical activity of muscles. In the test, small electrodes are placed on or in the skin; the patterns of electrical activity are projected on a screen or over a loudspeaker. This procedure is used to test for muscle disorders, including muscular dystrophy.

Inflammation—A protective response of injured tissues characterized by redness, increased heat, swelling, and/or pain in the affected area.

Voluntary muscles—Muscles producing voluntary movement.

Treatment

Treatment depends on the specific type of myopathy the person has:

- periodic paralysis: medication and dietary changes
- hyperthyroid or hypothyroid myopathy: treatment of the underlying thyroid abnormality
- myositis ossificans: medication may prevent abnormal bone formation, but there is no cure following onset
- central core disease: no treatment
- nemaline myopathy: no treatment
- centronuclear (myotubular) myopathy: no treatment
- paramyotonia congenita: treatment often unnecessary
- myotonia congenita: drug treatment (if necessary), but drugs do not affect the underlying disease, and attacks may still occur

Prognosis

The prognosis for patients with myopathy depends on the type and severity of the individual disease. In most cases, the myopathy can be successfully treated and the patient returned to normal life.

Muscular dystrophy, however, is generally a much more serious condition. Duchenne's MD is usually fatal by the late teens; Becker's MD is less serious and may not be fatal until the 50s.

Myopia

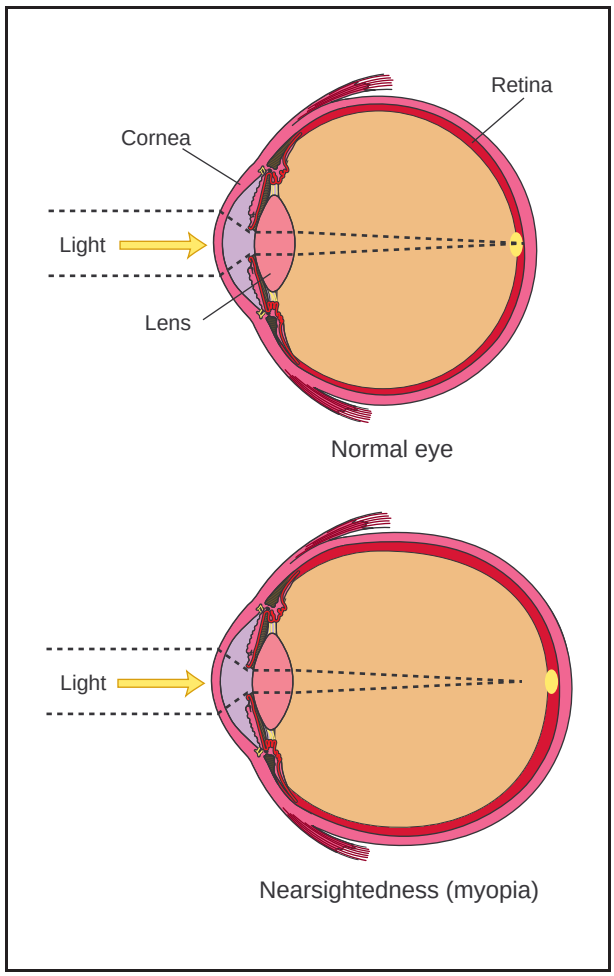
Definition

Myopia is the medical term for nearsightedness. People with myopia see objects more clearly when they are close to the eye, while distant objects appear blurred or fuzzy. Reading and close–up work may be clear, but distance vision is blurry.

Description

To understand myopia it is necessary to have a basic knowledge of the main parts of the eye's focusing system: the cornea, the lens, and the retina. The cornea is a tough, transparent, dome-shaped tissue that covers the front of the eye (not to be confused with the white, opaque sclera). The cornea lies in front of the iris (the colored part of the eye). The lens is a transparent, double-convex structure located behind the iris. The retina is a thin membrane that lines the rear of the eyeball. Light-sensitive retinal cells convert incoming light rays into electrical signals that are sent along the optic nerve to the brain, which then interprets the images.

In people with normal vision, parallel light rays enter the eye and are bent by the cornea and lens (a process called refraction) to focus precisely on the retina, providing a crisp, clear image. In the myopic eye, the focusing power of the cornea (the major refracting structure of the eye) and the lens is too great with respect to the length of the eyeball. Light



Myopia, or nearsightedness, is a condition of the eye in which objects are seen more clearly when close to the eye while distant objects appear blurred or fuzzy. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

rays are bent too much, and they converge in front of the retina. This inaccuracy is called a refractive error. In other words, an overfocused fuzzy image is sent to the brain.

There are many types of myopia. Some common types include:

- physiologic
- pathologic
- acquired

By far the most common form, physiologic myopia develops in children sometime between the ages of five and 10 years and gradually progresses until the eye is fully grown. Physiologic myopia may include refractive myopia (the cornea and lens-bending properties are too strong) and axial myopia (the eyeball is too long). Pathologic myopia is a far less common abnormality. This condition begins as physiologic myopia, but rather than stabilizing, the eye continues to enlarge at an abnormal rate (progressive myopia). This more advanced type of myopia may lead to degenerative changes in the eye (degenerative myopia). Acquired myopia occurs after infancy. This condition may be seen in association with uncontrolled diabetes and certain types of **cataracts**. **Antihypertensive drugs** and other medications can also affect the refractive power of the lens.

Genetic profile

Eye care professionals have debated the role of genetics in the development of myopia for many years. Some believe that a tendency toward myopia may be inherited but that the actual disorder results from a combination of environmental and genetic factors. Environmental factors include close work; work with computer monitors or other instruments that emit some light (electron microscopes, photographic equipment, lasers, etc.); emotional **stress**; and eye strain.

A variety of genetic patterns for inheriting myopia have been suggested, ranging from a recessive pattern with complete penetrance in people who are homozygotic for myopia to an autosomal dominant pattern; an autosomal recessive pattern; and various mixtures of these patterns. One explanation for this lack of agreement is that the genetic profile of high myopia (defined as a refractive error greater than 6 diopters) may differ from that of low myopia. Some researchers believe that high myopia is determined by genetic factors to a greater extent than low myopia.

The lack of clear consensus concerning the role of heredity in myopia may be due to the sensitivity of the human eye to very small changes in its anatomical structure. Since even small deviations from normal structure cause significant refractive errors, it may be difficult to single out any specific genetic or environmental factor as their cause.

Genetic markers and gene mapping

Since 1992, genetic markers that may be associated with genes for myopia have been located on human chromosomes 1, 2, 12, and 18. There is some genetic information on the short arm of chromosome 2 in highly myopic people. Genetic information for low myopia appears to be located on the short arm of chromosome 1, but it is not known whether this information governs the structure of the eye itself or vulnerability to environmental factors.

WWW.BOOKBAZ.IR

In 1998, a team of American researchers presented evidence that a gene for familial high myopia with an autosomal dominant transmission pattern could be mapped to human chromosome 18 in eight North American families. The same group also found a second locus for this form of myopia on human chromosome 12 in a large German/Italian family. In 1999, a group of French researchers found no linkage between chromosome 18 and 32 French families with familial high myopia. These findings have been taken to indicate that more than one gene is involved in the transmission of the disorder.

As of 2009, the heritability of high-grade myopia had been confirmed. Multiple high-grade myopia genetic loci have been identified, and confirmatory studies identifying high–grade and moderate myopia loci have also occurred. However, myopia susceptibility genes still remain unknown.

Family studies

It has been known for some years that a family history of myopia is one of the most important risk factors for developing the condition. Only 6–15% of children with myopia come from families in which neither parent is myopic. In families with one myopic parent, 23–40% of the children develop myopia. If both parents are myopic, the rate rises to 33–60% for their children. One American study found that children with two myopic parents are six times as likely to develop myopia themselves as children with only one or no myopic parents. The precise interplay of genetic and environmental factors in these family patterns, however, is not yet known.

One multigenerational study of Chinese patients indicated that third generation family members had a higher risk of developing myopia even if their parents were not myopic. The researchers concluded that, at least in China, the genetic factors in myopia have remained constant over the past three generations while the environmental factors have intensified. The increase in the percentage of people with myopia over the last 50 years in the United States has led American researchers to the same conclusion.

Demographics

The prevalence of refractive error in the United States has not been evaluated since the early 1970s. According to a 2006 study sponsored by the National Eye Institute (NEI), refractive errors are estimated to affect 42.2 million (35%) of Americans 40 years or older.

Myopia is the most common eye disorder in humans around the world. It affects some 20% of the adult population in the United States. In various reports, incidence frequently varies with age, sex, race, ethnicity, occupation, environment, and other factors. Myopia is more common in central and eastern Europe than in northern Europe, Britain, and the United States. It is also very common in certain populations, such as Chinese, Japanese, Arab, and Jewish persons. Myopia is uncommon in black, Nubian, and Sudanese persons.

Other factors that affect the demographic distribution of myopia are income level and education. The prevalence of myopia is higher among people with above–average incomes and educational attainments. Myopia is also more prevalent among people whose work requires a great deal of close focusing, including work with computers.

Signs and symptoms

Myopia is said to be caused by an elongation of the eyeball. This means that the oblong (as opposed to normal spherical) shape of the myopic eye causes the cornea and lens to focus at a point in front of the retina. A more precise explanation is that there is an inadequate correlation between the focusing power of the cornea and lens and the length of the eye.

People are generally born with a small amount of **hyperopia** (farsightedness), but as the eye grows this decreases and myopia does not become evident until later. This change is one reason why some researchers think that myopia is an acquired rather than an inherited trait.

The symptoms of myopia are blurred distance vision, eye discomfort, squinting, and eye strain.

Diagnosis

The diagnosis of myopia is typically made during the first several years of elementary school when a teacher notices a child having difficulty seeing the chalkboard, reading, or concentrating. The teacher or school nurse often recommends an **eye examination** by an ophthalmologist or optometrist. An ophthalmologist—M.D. or D.O. (Doctor of Osteopathy)—is a medical doctor trained in the diagnosis and treatment of eye problems. Ophthalmologists also perform eye surgery. An optometrist (O.D.) diagnoses, manages and/or treats eye and visual disorders. In many states, optometrists are licensed to use diagnostic and therapeutic drugs.

KEY TERMS

Accommodation—The ability of the lens to change its focus from distant to near objects. It is achieved through the action of the ciliary muscles that change the shape of the lens.

Cornea—The transparent structure of the eye over the lens that is continous with the sclera in forming the outermost, protective, layer of the eye.

Diopter (D)—A unit of measure for describing refractive power.

Epi-LASIK—A surgical procedure that uses a blunt, plastic oscillating blade called an epithelial separator to cut a flap in the cornea.

Laser-assisted sub-epithelial keratomileusis (LASEK)—A surgical procedure in which the epithelium is loosened on the corneal surface. The loosened epithelium is then reflected away from the cornea, and laser ablation performed.

Laser-assisted in-situ keratomileusis (LASIK)—A surgical procedure that uses a cutting tool and a laser to modify the cornea and correct moderate to high levels of myopia.

Lens—The transparent, elastic, curved structure behind the iris (colored part of the eye) that helps focus light on the retina.

Ophthalmologist—A physician specializing in the medical and surgical treatment of eye disorders.

Optic nerve—A bundle of nerve fibers that carries visual messages from the retina in the form of electrical signals to the brain.

Optometrist—A medical professional who examines and tests the eyes for disease and treats visual disorders by prescribing corrective lenses and/or vision therapy. In many states, optometrists are licensed to use diagnostic and therapeutic drugs to treat certain ocular diseases.

Orthokeratology—A method of reshaping the cornea using a contact lens. It is not considered a permanent method to reduce myopia.

Peripheral vision—The ability to see objects that are not located directly in front of the eye. Peripheral vision allows people to see objects located on the side or edge of their field of vision.

Photorefractive keratectomy (PRK)—A procedure that uses an excimer laser to make modifications to the cornea and permanently correct myopia. As of early 1998, only two lasers had been approved by the FDA for this purpose.

Radial keratotomy (RK)—A surgical procedure involving the use of a diamond-tipped blade to make several spoke-like slits in the peripheral (non-viewing) portion of the cornea to improve the focus of the eye and correct myopia by flattening the cornea.

Refraction—The bending of light rays as they pass from one medium through another; used to describe the action of the cornea and lens on light rays as they enter they eye; also used to describe the determination and measurement of the eye's focusing system by an optometrist or ophthalmologist.

Refractive eye surgery—A general term for surgical procedures that can improve or correct refractive errors by permanently changing the shape of the cornea.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Visual acuity—The ability to distinguish details and shapes of objects.

A patient's distance vision is tested by reading letters or numbers on a chart posted a set distance away (usually 20 ft). The doctor asks the patient to view images through a variety of lenses to obtain the best correction. The doctor also examines the inside of the eye and the retina. An instrument called a slit lamp is used to examine the cornea and lens. The eyeglass prescription is written in terms of diopters (D), which measure the degree of refractive error. Mild to moderate myopia usually falls between -1.00D and -6.00D. Normal vision is commonly referred to as 20/20 to describe the eye's focusing ability at a distance of 20 feet from an object. For example, 20/50 means that a myopic person must stand 20 feet away from an eye chart to see what a normal person can see at 50 feet. The larger the bottom number, the greater the myopia.

Treatment and management

People with myopia have three main options for treatment: optical devices, such as eyeglasses and **contact lenses**, refractive eye surgery, and intraocular surgical procedures.

WWW.BOOKBAZ.IR

Optical devices

EYEGLASSES. Eyeglasses are the most common method used to correct myopia. Concave glass or plastic lenses are placed in frames in front of the eyes. The lenses are ground to the thickness and curvature specified in the eyeglass prescription. The lenses cause the light rays to diverge so that they focus further back, directly on the retina, producing clear distance vision.

CONTACT LENSES. Contact lenses are a second option for treatment. Contact lenses are extremely thin round discs of plastic that are worn on the eye in front of the cornea. Although there may be some initial discomfort, most people quickly grow accustomed to contact lenses. Hard contact lenses, made from a material called PMMA, are virtually obsolete. Rigid gas permeable lenses (RGP) are made of plastic that holds its shape but allows the passage of some oxygen into the eye. Some believe that RGP lenses may halt or slow the progression of myopia because they maintain a constant, gentle pressure that flattens the cornea. In 2004, results of a NEI-sponsored study called the Contact Lens and Myopia Progression (CLAMP) Study, were published. Researchers found that RGP contact lenses slowed the progression of myopia in young children. Researchers also found that RGP contact lenses did not slow the growth of the eye, responsible for the majority of myopia in children. Instead of slowing the growth of the eye, RGP lenses kept the cornea from changing shape more than soft contact lenses.

Soft contact lenses are made of flexible plastic and can be up to 80% water. Soft lenses offer increased comfort and the advantage of extended wear; some can be worn continuously for up to one week. While oxygen passes freely through soft lenses, bacterial contamination and other problems can occur, requiring replacement of lenses on a regular basis. It is very important to follow the cleaning and disinfecting regimens prescribed because protein and lipid buildup can occur on the lenses, causing discomfort or increasing the risk of infection. Contact lenses offer several benefits over glasses, including: better vision, less distortion, clear peripheral vision, and cosmetic appeal. In addition, contacts will not fog up from perspiration or changes in temperature.

Refractive eye surgery

For people who find glasses and contact lenses inconvenient or uncomfortable and who meet selection criteria regarding age, degree of myopia and general health, refractive eye surgery is a third treatment alternative. **Radial keratotomy** was the first such procedure developed, but has been replaced since the mid-1990s by **photorefractive keratectomy** (PRK), laser-assisted in-situ keratomileusis (**LASIK**), Epi-LASIK, and laser-assisted sub-epithelial keratomileusis (LASEK). Refractive eye surgery improves myopic vision by permanently changing the shape of the cornea so that light rays focus properly on the retina. These procedures are performed on an outpatient basis and generally take 10–30 minutes.

PHOTOREFRACTIVE KERATECTOMY (PRK). PRK involves the use of a computer to measure the shape of the cornea. Using these measurements, the surgeon uses a computer-controlled excimer laser to make modifications to the cornea. The PRK procedure flattens the cornea by vaporizing small amounts of tissue from the cornea's surface, thereby improving the cornea's refractive properties in focusing light on the retina. The ultra thin, outer layer of the eye (epithelium) is removed completely by laser energy during the PRK procedure, and eventually grows back. PRK has been approved by the Food and Drug Administration (FDA) for myopia since 1995 and the first excimer lasers used to perform PRK have been improved significantly in terms of size, efficiency, and accuracy. PRK can treat mild to moderate forms of myopia.

LASER-ASSISTED IN-SITU KERATOMILEUSIS (LASIK). LASIK has been approved by the FDA for several different laser platforms. About 5 million procedures have been performed in the United States since the approval of the excimer laser for refractive surgery in late 1995. It is recommended for moderate to severe cases of myopia. As practiced in the early 2000s, LASIK is perhaps best thought of as PRK performed under a flap instead of on the corneal surface. The flap is flipped back to expose the inner layers of the cornea. The cornea is treated with a laser to change the shape and focusing properties,then the flap is replaced. For myopic LASIK ablations, most of the laser energy is directed at the center of the treatment zone with the result that the central cornea is thus flattened.

LASER-ASSISTED SUB-EPITHELIAL KERATOMILEUSIS (LASEK). In a LASEK procedure, the epithelium is chemically loosened using dilute alcohol on the corneal surface. The loosened epithelium is then reflected away from the cornea, and laser ablation performed. The procedure preserves the extremely thin epithelial layer by lifting it from the eye's surface before using a laser for reshaping. After the LASEK procedure, the epithelium is replaced on the eye's surface.

EPI-LASIK. In Epi-LASIK, the surgeon uses a blunt, plastic oscillating blade called an epithelial separator to cut a flap in the cornea. Instead of the alcohol used in LASEK to loosen the epithelial sheet, the epithelial separator is used to separate the sheet from the eye. This avoids the possibility of an adverse reaction from the alcohol. Because it is more difficult to create the epithelial flap in people with steeper corneas (who have higher amounts of myopia), the procedure is considered more appropriate for people with less steep corneas (who have low myopia).

Intraocular surgical procedures

These procedures involve extraction of the clear lens with or without lens implantation and the use of intraocular lens (IOL) implants. IOLs have been used since 1999 for correcting large refractive errors in myopia. An IOL is a microscopic lens that can be placed inside the eye to correct certain vision problems. For patients who are extremely nearsighted and may have contraindications to LASIK, an IOL may be implanted in front of the iris to correct their distance vision and provide normal focusing ability and near vision. Although IOLs are intended to be permanent, the procedure is reversible.

Risks

All of these surgical procedures carry risks, the most serious being corneal scarring, corneal rupture, infection, flap problems, dry eye, cataracts, and loss of vision. The National Eye Institute (NEI) warns that before agreeing to refractive surgery, patients should fully understand what they can expect. Surgeons should explain the risks and possible complications, as well as potential side effects.

Since refractive eye surgery does not guarantee 20/20 vision, it is important to have realistic expectations before choosing this treatment. For example, the American Academy of Ophthalmology (AAO) reports that nine out of 10 patients achieve 20/20 vision, but 20/20 does not always mean perfect vision. Detailed, precise vision may be slightly diminished. Even if the patient gains near-perfect vision, irritating side effects are also possible, such as postoperative **pain**, poor night vision, variation in visual acuity, light sensitivity and glare, and optical distortion. Finally, refractive eye surgeries are considered elective procedures and are rarely covered by insurance plans.

Alternatives

Some eye care professionals recommend treatments to help improve circulation, reduce eye strain, and relax the eye muscles. It is possible that by combining exercises with changes in behavior, the progression of myopia may be slowed or prevented. Alternative treatments include: visual therapy (also referred to as **vision training** or eye exercises); discontinuing close work; reducing eye strain (taking a rest break during periods of prolonged near vision tasks); and wearing bifocals to decrease the need to accommodate when doing close-up work.

Clinical trials

Clinical trials on myopia are currently sponsored by the National Institutes of Health (NIH) and other agencies. As of 2015, NIH was reporting 420 on-going and completed studies.

Examples include:

- The evaluation of neurovision correction (NVC) technology for the treatment of low myopia (NCT00469612)
- A study of the inheritance of myopia in families of various nationalities and ethnic backgrounds to identify gene changes that cause myopia or similar diseases (NCT00272376)
- A study to determine whether the MEL 80 Excimer Laser is effective in the treatment of moderate to high myopia, when used as part of the LASIK procedure (NCT00762541)

Clinical trial information is constantly updated by NIH and the most recent information on myopia trials can be found at: http://clinicaltrials.gov/ct2/results?term=myopia

Prognosis

Glasses and contact lenses can (but not always) correct the patient's vision to 20/20. Refractive surgery can make permanent improvements for the right candidates.

While the genetic factors that influence the transmission and severity of myopia cannot be changed, some environmental factors can be modified. They include reducing close work; reading and working in good light; taking frequent breaks when working at a computer or microscope for long periods of time; maintaining good **nutrition**; and practicing visual therapy (when recommended).

Eye strain can be prevented by using sufficient light for reading and close work, and by wearing corrective lenses as prescribed. People should have regular eye examinations to see if their prescription has changed or if any other problems have developed. This is particularly important for people with high

WWW.BOOKBAZ.IR

(degenerative) myopia who are at a greater risk of developing **retinal detachment**, retinal degeneration, **glaucoma**, or other problems.

Rebecca J. Frey, PhD

Myositis

Definition

Myositis is a rare disease in which the muscle fibers and skin are inflamed and damaged, resulting in muscle weakness. There are several types of myositis that affect different parts of the body.

Description

The persistent inflammation that is associated with myositis develops slowly over weeks to months and often years, with progressive weakening of the muscles. Later in the course of the disease development muscle wasting or shortening (contracture) may develop. Myositis can range in severity from mild to debilitating.

The forms of myositis include:

- Polymyositis (PM) inflames and weakens muscles in many parts of the body, and especially those parts closest to the trunk. With polymyositis, dysphagia (difficulty, discomfort, or pain in speaking or swallowing), fatigue, and pain in the muscles are common. PM rarely affects people under the age of 20, with the peak onset between the ages of 30 and 60.
- Dermatomyositis (DM) affects both the muscle fibers and skin by damaging the tiny blood vessels (capillaries) that supply blood to the muscle and skin, resulting in muscle weakness, pain, and fatigue. In addition the affected person develops a distinctive patchy, reddish rash on the eyelids, cheeks, bridge of the nose, back or upper chest, elbows, knees, and knuckles. There may also be hardened, tender bumps (possibly caused by inflammation of fat) under the skin. DM can occur at any age and is more common in females than males.
- Inclusion Body Myositis (IBM) typically begins after age 50 and is characterized by gradual weakening of muscles throughout the body, including the wrists or

fingers, development of dysphagia, and atrophy of forearms and/or thigh muscles. Unlike the other types of myositis, IBM occurs more often in men than women, and also does not respond very well to drug therapy.

- Juvenile myositis (JM) involves muscle weakness, skin rash, and dysphagia in children. A common characteristic of JM is the formation of calcium deposits in the muscle (calcinosis). These deposits are hard and sometimes painful lumps of calcium under the skin that appear on the child's fingers, hands, elbows, and knees. Painful sores may appear if the lumps break through the skin. The child may also suffer from contractures, which is muscle shortening that results in joints staying bent. About half of the children with JM will have pain in their muscles.

Myositis is rare, affecting about 10 in one million people each year. DM and PM affect mostly women in their forties and fifties but men and children can also affect be affected, some at a young age (between the ages of 5 and 15). About 40,000 people in the United States may have this disease, with about 3,000 to 5,000 children affected.

Causes and symptoms

Myositis is thought to be an autoimmune disease. The body normally fights infections and disease by producing antibodies and white blood cells called lymphocytes in a process called the immune response. In an autoimmune disease, the immune response is overactive, and the immune system attacks and destroys the body's own normal healthy tissues. There is no known cause to the autoimmune response that results in myositis. However, investigators are studying whether the disease is triggered by such environmental agents as the organism that causes **toxoplasmosis**, *Toxoplasma gondii*, the **Lyme disease** organism, *Borrelia burgdorferi*, the coxsackievirus, or by **food allergies**. Some cases of IBM are thought to be inherited.

The first symptoms of most types of myositis are weakness and **pain** in the muscles of the hips and shoulders. The affected person may have trouble getting up from a chair, lifting the arms above the head, or climbing stairs, and may be too tired to walk or stand. DM and PM mostly affects muscles that are close to and within the trunk of the body, while IBM involves a wider range of muscles. Myositis may make it difficult for the person to speak or swallow. When the disease affects the lungs or chest muscles, the person may have difficulty breathing. If the person has DM, they may develop characteristic **rashes**. Other symptoms may include **fever** and joint pain and swelling.

The first signs of JM is usually a red and patchy skin rash and/or a red or purplish rash on the eyelids or cheeks that look like **allergies**. Weak muscles may develop at the same time as the rash, or may develop days, weeks, or months after the appearance of the rash. Other symptoms of JM include falling, a weaker voice (dysophonia), or dysphagia. Calcinosis usually develops later during the course of the disease.

Diagnosis

Myositis can a difficult disease to diagnose, because it is rare, because the symptoms develop slowly, and because it can be mistaken for other diseases causing muscle weakness such as limb-girdle **muscular dystrophy**. Many cases of myositis go undiagnosed for years. The healthcare provider must rule out other conditions such as **hypothyroidism**, toxin exposure, drug reactions, and genetic disorders that can also affect muscles. The **physical examination** will include a complete medical history focusing on symptoms and when they occurred, and blood tests for autoantibodies and muscle enzymes (for example, creatine kinase (CK), which when present in the blood indicates muscle damage). Specialized tests may also be performed, including:

- an electromyogram, which measures the electrical pattern of the muscles
- a muscle biopsy, in which a small piece of muscle is removed, stained, and examined by microscopic techniques to determine if muscle fibers are damaged and whether the muscle fibers are being infiltrated by cells of the immune system
- magnetic resonance imaging (MRI) to identify areas of muscle inflammation

Treatment

There is no cure for myositis. However, prompt and aggressive treatment may reduce muscle inflammation and prevent muscle weakness from progressing. Because of the many different kinds of symptoms and a wide range of reactions to different drugs, each person's treatment for myositis should be individualized.

Drugs that are used for treatment include **corticosteroids**, such as prednisone, to reduce inflammation and improve the body's reaction to infections. Corticosteroids are usually taken in the form of pills, but may also be injected. The amount of creatine kinase (CK) levels in the blood are monitored to

WWW.BOOKBAZ.IR

determine how well the medicine is working. Corticosteroids may produce a number of side effects, such as weight gain, difficulties in fighting infections, psychiatric changes, sleeping troubles, water retention, bone thinning, facial swelling, diabetes, and **cataracts**. Corticosteroid therapy usually leads to improvement in myositis symptoms within two to three months, after which the dose can be lowered to avoid the side effects. If the dose of corticosteriods is going to be reduced, it is essential to lower the dose over a period of time.

Immunosuppressant drugs are used to slow down the immune system's attack on healthy tissue and improve skin rashes. Persons may be prescribed these drugs to control myositis if they are unable to tolerate corticosteroids or if the corticosteroids are not accomplishing the desired degree of treatment. Immunosuppressant drugs may also be used in conjunction with corticosteroids so that lower doses of corticosteroids can be used. Immunosuppressant drugs include azathioprine, methotrexate, cyclosporine, tacrolimus, etanercept, and mycophenolate mofetil.

Intravenous immunoglobulin (IVIg) appears to aid in improving muscle strength in many persons with myositis, particularly those with DM. It may be less effective in PM, and its role in treating IBM requires more study, although it has been shown to help some patients with IBM if they are diagnosed early. Immunoglobulins are normal proteins in the blood that attack anything foreign in the body, such as viruses and bacteria. IVIg is made from donated blood plasma from people with normal immune systems. Side effects from the the use of IVIg include **headache** and flu-like symptoms.

Topical cream or ointment forms of some of the medicines, such as prednisone and tacrolimus, can be used to heal and soothe the rash associated with DM. Non-steriodal anti-inflammatory drugs (NSAIDS) such as **aspirin** or ibuprofen can be used for pain relief. Calcinosis can be treated with prednisone, plaquenil (also called hydroxychloroquine), intravenous immunoglobin (IVIG), cyclosporine, and methotrexate.

After drug treatment results in improvement, the affected person begins a program of regular stretching exercises to maintain range of motion in the weakened arms and legs. **Physical therapy** may be used to prevent permanent muscle shortening. Whirlpool baths, heat, and gentle massages may also provide relief. Adequate rest is necessary, and affected persons should take frequent breaks throughout the day and limit their activity.

Patients with throat problems should be evaluated by a speech therapist who can evaluate the swallowing-related problems and make recommendations regarding diet changes and safe swallowing techniques.

Before a woman with myositis becomes pregnant, she should discuss the medicines that she is taking with her healthcare provider and evaluate the possible risks that she and the baby face if she does become pregnant. Many of the drugs used in the treatment of myositis may be harmful to the fetus or to a breastfed baby.

It is recommended that a doctor experienced in the treatment of myositis, assisted by a rheumatologist, dermatologist, or neurologist, be consulted. Oftentimes a patient may have to be treated at a major medical center, where the disease has been seen and treated before.

Alternatives

Various supplements may be used in conjunction with traditional treatment to offset side effects of conventional drug treatment. The use of these suppplements should be approved by the primary healthcare provider.

Immunosuppressant drugs such as methotroxate and cyclophosphamide increase the risk of infection, so a healthy well-balanced diet is required. Methotroxate impairs the body's ability to absorb **folic acid**, so foods high in folic acid, such as leafy green vegetables, fruits, and folate-fortified breads and cereals are recommended. The use of folate supplements may also be recommended by the health care provider. **Vitamins** C and E can be used to help with the pain and infections associated with calcinosis.

Corticosteroids may have multiple side effects when taken for long periods of time at high doses. **Calcium** and **Vitamin D** are recommended to lower the risk of **osteoporosis**, a common side effect of prednisone use. **Hypertension** and fluid retention may be controlled by a diet low in salt. Steroid-induced diabetes (hyperglycemia) can be aided by a diet low in sugar and other simple carbohydrates. Proteinuria, in which the body breaks down protein faster than normal, may mean that more protein should be included in the diet.

Weight gain associated with the use of corticosteroids can be managed by the use of the DASH (Dietary Approach to Stop Hypertension) diet, which is high in fruits, vegetables, dietary fiber, and low-fat dairy products. Information concerning this

KEY TERMS

Coxsackievirus—Enterovirus causing a disease resembling poliomyelitis but without paralysis.

Dysphagia—Medical term for any difficulty, discomfort, or pain when swallowing.

Limb-girdle muscular dystrophy—An autosomal recessive form of muscular dystrophy that appears anywhere from late childhood to middle age and is characterized by progressive muscular weakness beginning either in the shoulder or pelvic girdle; the disease usually progresses slowly with cardiopulmonary complications in the later stages.

diet, developed by the National Institutes of Health, can be found at [htpp://www.nhlbi.nih.gov/health/public/heart/hbp/dash/]. Weight gain can overtax weakened muscles and should be avoided if possible.

Prognosis

The progression of PM and DM varies from person to person, but the lifespan of an affected person is not usually significantly affected. DM responds more favorably to therapy than PM. Overall, many patients do improve and have a functional recovery. About half of the patients recover and can discontinue treatment within 5 years of beginning treatment. In children the chances of a cure are better than in adults, although some children do suffer a relapse. Of the remaining 50%, about 20% will still have the active disease and will require ongoing treatment, while up to 30% may have some remaining muscle weakness. However, IBM is disabling, and most patients will require the use of an assistive device such as a cane, walker, or wheel chair. The older the patient is when contracting IBM, the more rapidly the disease progresses.

Prevention

There is no known way to prevent myositis.

Myotonic dystrophy

Definition

Myotonic dystrophy is a progressive disease in which the muscles are weak and are slow to relax after contraction.

Demographics

DM occurs in about 1 per 7,000–8,000 people and has been described in people from all over the world. DM is an inherited disease, affecting males and females approximately equally. About 30,000 people in the United States are affected.

Description

Myotonic dystrophy (DM), also called dystrophia myotonica, myotonia atrophica, or Steinert's disease, is a common form of **muscular dystrophy**. Symptoms may appear at any time from infancy to adulthood. DM causes general weakness, usually beginning in the muscles of the hands, feet, neck, or face. It slowly progresses to involve other muscle groups, including the heart. DM affects a wide variety of other organ systems as well.

A severe form of DM, congenital myotonic dystrophy or Thomsen's disease, may appear in newborns of mothers who have DM. *Congenital* means that the condition is present from birth. The incidence of congenital myotonic dystrophy is thought to be about 1:20,000.

WWW.BOOKBAZ.IR

Risk factors

The most common type of DM is called DM1 and is caused by a mutation in a gene called myotonic dystrophy protein kinase (DMPK). The DMPK gene is located on chromosome 19q. When there is a mutation in this gene, a person develops DM1. The specific mutation that causes DM1 is called a trinucleotide repeat expansion. Risk for DM increases when a parent has a mutation in this gene.

Causes and symptoms

Some families with symptoms of DM do not have a mutation in the DMPK gene. Scientists have found that the DM in many of these families is caused by a mutation in a gene on chromosome 3. These families are said to have DM2.

Congenital myotonic dystrophy has been linked to a region on chromosome 7 that contains a muscle chloride channel gene.

Trinucleotide repeats

In the DMPK gene, there is a section of the genetic code called a CTG repeat. The letters stand for three nucleotides (complex organic molecules) known as cytosine, thymine, and guanine, and are repeated a certain number of times. In people who have DM1, this sequence of nucleotides is repeated too many times—more than the normal number of 37 times—making this section of the gene too big. This enlarged section of the gene is called a trinucleotide repeat expansion.

People who have repeat numbers in the normal range will not develop DM1 and cannot pass it to their children. Having more than 50 repeats causes DM1. People who have 38–49 repeats have a premutation and will not develop DM1, but can pass DM1 onto their children. Having repeats numbers greater than 1,000 causes congenital myotonic dystrophy.

In general, the more repeats in the affected range that someone has, the earlier the age of onset of symptoms and the more severe the symptoms. However, this is a general rule. It is not possible to look at individuals' repeat number and predict at what age they will begin to have symptoms or how their condition will progress.

Exactly how the trinucleotide repeat expansion causes myotonia, the inability to relax muscles, is not yet understood. The disease somehow blocks the flow of electrical impulses across the muscle cell membrane. Without proper flow of charged particles, the muscle cannot return to its relaxed state after it has contracted.

In the early 2000s, DM2 was determined to be caused by a CCTG (cytosine-cytosine-thymine-guanine) expansion on chromosome 3 at locus 3q21, but it is not known how this repeat affects muscle cell function.

Anticipation

Sometimes when a person who has repeat numbers in the affected or premutation range has children, the expansion grows larger. This is called anticipation. A larger expansion can result in an earlier age of onset in children than in their affected parent. Anticipation happens more often when a mother passes DM1 onto her children then when it is passed from the father. Occasionally, repeat sizes stay the same or even get smaller when they are passed to a person's children.

Inheritance

DM is inherited through autosomal dominant inheritance. This means that equal numbers of males and females are affected. It also means that only one gene in the pair needs to have the mutation in order for a person to be affected. Since a person only passes one copy of each gene onto their children, there is a 50% or one in two chance that a person who has DM will pass it onto each of their children. This percentage is not changed by results of other pregnancies. A person with a premutation also has a 50%, or one in two, chance of passing the altered gene on to each of their children. Whether or not their children will develop DM1 depends on whether the trinucleotide repeat becomes further expanded. A person who has repeat numbers in the normal range cannot pass DM1 onto their children.

There is a range in the severity of symptoms in DM and not everyone will have all of the symptoms.

Myotonic dystrophy causes weakness and delayed muscle relaxation called myotonia. Symptoms of DM include facial weakness and a slack jaw, drooping eyelids called **ptosis**, and muscle wasting in the forearms and calves. Persons with DM have difficulty relaxing their grasp, especially in the cold. DM affects the heart muscle, causing irregularities in the heartbeat. It also affects the muscles of the digestive system, causing **constipation** and other digestive problems. DM may cause **cataracts**, retinal degeneration, low IQ, frontal balding, skin disorders, atrophy of the testicles, and diabetes. It can also cause sleep apnea—a condition in which normal breathing is interrupted during sleep. DM increases the need for sleep and decreases motivation. Severe disabilities do not set in until about 20 years after symptoms begin.

KEY TERMS

Electrocardiogram (ECG, EKG)—A test that uses electrodes attached to the chest with an adhesive gel to transmit the electrical impulses of the heart muscle to a recording device.

Electromyography (EMG)—A test that uses electrodes to record the electrical activity of muscle. The information gathered is used to diagnose neuromuscular disorders.

Muscular dystrophy—A group of inherited diseases characterized by progressive wasting of the muscles.

Nucleotide—Any of a group of organic molecules that link together to form the building blocks of DNA or RNA.

Sleep apnea—Temporary cessation of breathing while sleeping.

Trinucleotide repeat expansion—A sequence of three nucleotides that is repeated too many times in a section of a gene.

Most people with myotonic dystrophy maintain the ability to walk, even late in life.

A severe form of DM, congenital myotonic dystrophy, may appear in newborns of mothers who have DM1. Congenital myotonic dystrophy is marked by severe weakness, poor sucking and swallowing responses, respiratory difficulty, delayed motor development, and **intellectual disability** (ID). Death in infancy is common in this type.

Some people who have a trinucleotide repeat expansion in their DMPK gene do not have symptoms or have very mild symptoms that go unnoticed. It is not unusual for a woman to be diagnosed with DM after she has an infant with congenital myotonic dystrophy.

Predictive testing

It is possible to test someone who is at risk for developing DM1 before they are showing symptoms to see whether they inherited an expanded trinucleotide repeat. This is called predictive testing. Predictive testing cannot determine the age of onset that someone will begin to have symptoms, or the course of the disease.

Diagnosis

Diagnosis of DM is not difficult once the disease is considered. However, the true problem may be masked because symptoms can begin at any age, can be mild or severe, and can occur with a wide variety of associated complaints.

Examination

Diagnosis of DM begins with a careful medical history and a thorough physical exam to determine the distribution of symptoms and to rule out other causes. A family history of DM or unexplained weakness helps to establish the diagnosis.

Tests

A definitive diagnosis of DM1 is done by **genetic testing**, usually by taking a small amount of blood. The DNA in the blood cells is examined and the number of repeats in the DMPK gene is determined. Various other tests may be done to help establish the diagnosis, but only rarely would other testing be needed. An electromyogram (EMG) is a test is used to examine the response of the muscles to stimulation. Characteristic changes are seen in DM that helps distinguish it from other muscle diseases.

PRENATAL TESTING. Testing a **pregnancy** to determine whether an unborn child is affected is possible if genetic testing in a family has identified a DMPK mutation. This can be done at 10–12 weeks gestation by a procedure called **chorionic villus sampling** (CVS), which involves removing a tiny piece of the placenta and analyzing DNA from its cells. It can also be done by **amniocentesis** after 14 weeks gestation by removing a small amount of the amniotic fluid surrounding the baby and analyzing the cells in the fluid. Each of these procedures has a small risk of **miscarriage** associated with it and those who are interested in learning more should check with their doctor or genetic counselor.

Procedures

Removing a small piece of muscle tissue for microscopic examination is called a muscle biopsy. DM is marked by characteristic changes in the structure of muscle cells that can be seen on a muscle biopsy. An electrocardiogram could be performed to detect characteristic abnormalities in heart rhythm associated with DM. These symptoms often appear later in the course of the disease.

A procedure called preimplantation diagnosis allows a couple to have a child that is unaffected with the genetic condition in their family. This procedure is experimental and not widely available. Those interested in learning more about this procedure should check with their doctor or genetic counselor.

WWW.BOOKBAZ.IR

A group of researchers in Houston, Texas, reported in 2004 that they had successfully developed a technique for detecting the CCTG expansion that causes DM2 and estimating the size of the repeat expansion.

Treatment

Myotonic dystrophy cannot be cured, and no treatment can delay its progression. There is no standardized treatment for these disorders because the precise reasons for muscle weakness are not yet fully understood. However, many of the symptoms can be treated. **Physical therapy** can help preserve or increase strength and flexibility in muscles. Ankle and wrist braces can be used to support weakened limbs. **Occupational therapy** is used to develop tools and techniques to compensate for loss of strength and dexterity. A speech-language pathologist can provide retraining for weakness in the muscles controlling speech and swallowing.

Irregularities in the heartbeat may be treated with medication or a pacemaker. A yearly electrocardiogram is usually recommended to monitor the heartbeat. **Diabetes mellitus** in DM is treated in the same way that it is in the general population. A high-fiber diet can help prevent constipation. **Sleep apnea** may be treated with surgical procedures to open the airways or with nighttime ventilation. Treatment of sleep apnea may reduce drowsiness. Lens replacement surgery is available when cataracts develop. Pregnant woman should be followed by an obstetrician familiar with the particular problems of DM because complications can occur during pregnancy, labor and delivery.

Wearing a medical bracelet is advisable. Some emergency medications may have dangerous effects on the heart rhythm in a person with DM. Adverse reactions to general **anesthesia** may also occur.

Prognosis

The course of myotonic dystrophy varies. When symptoms appear earlier in life, disability tends to become more severe. Occasionally, people with DM require a wheelchair later in life. Children with congenital DM usually require special educational programs and physical and occupational therapy. For both types of DM, respiratory infections pose a danger when weakness becomes severe.

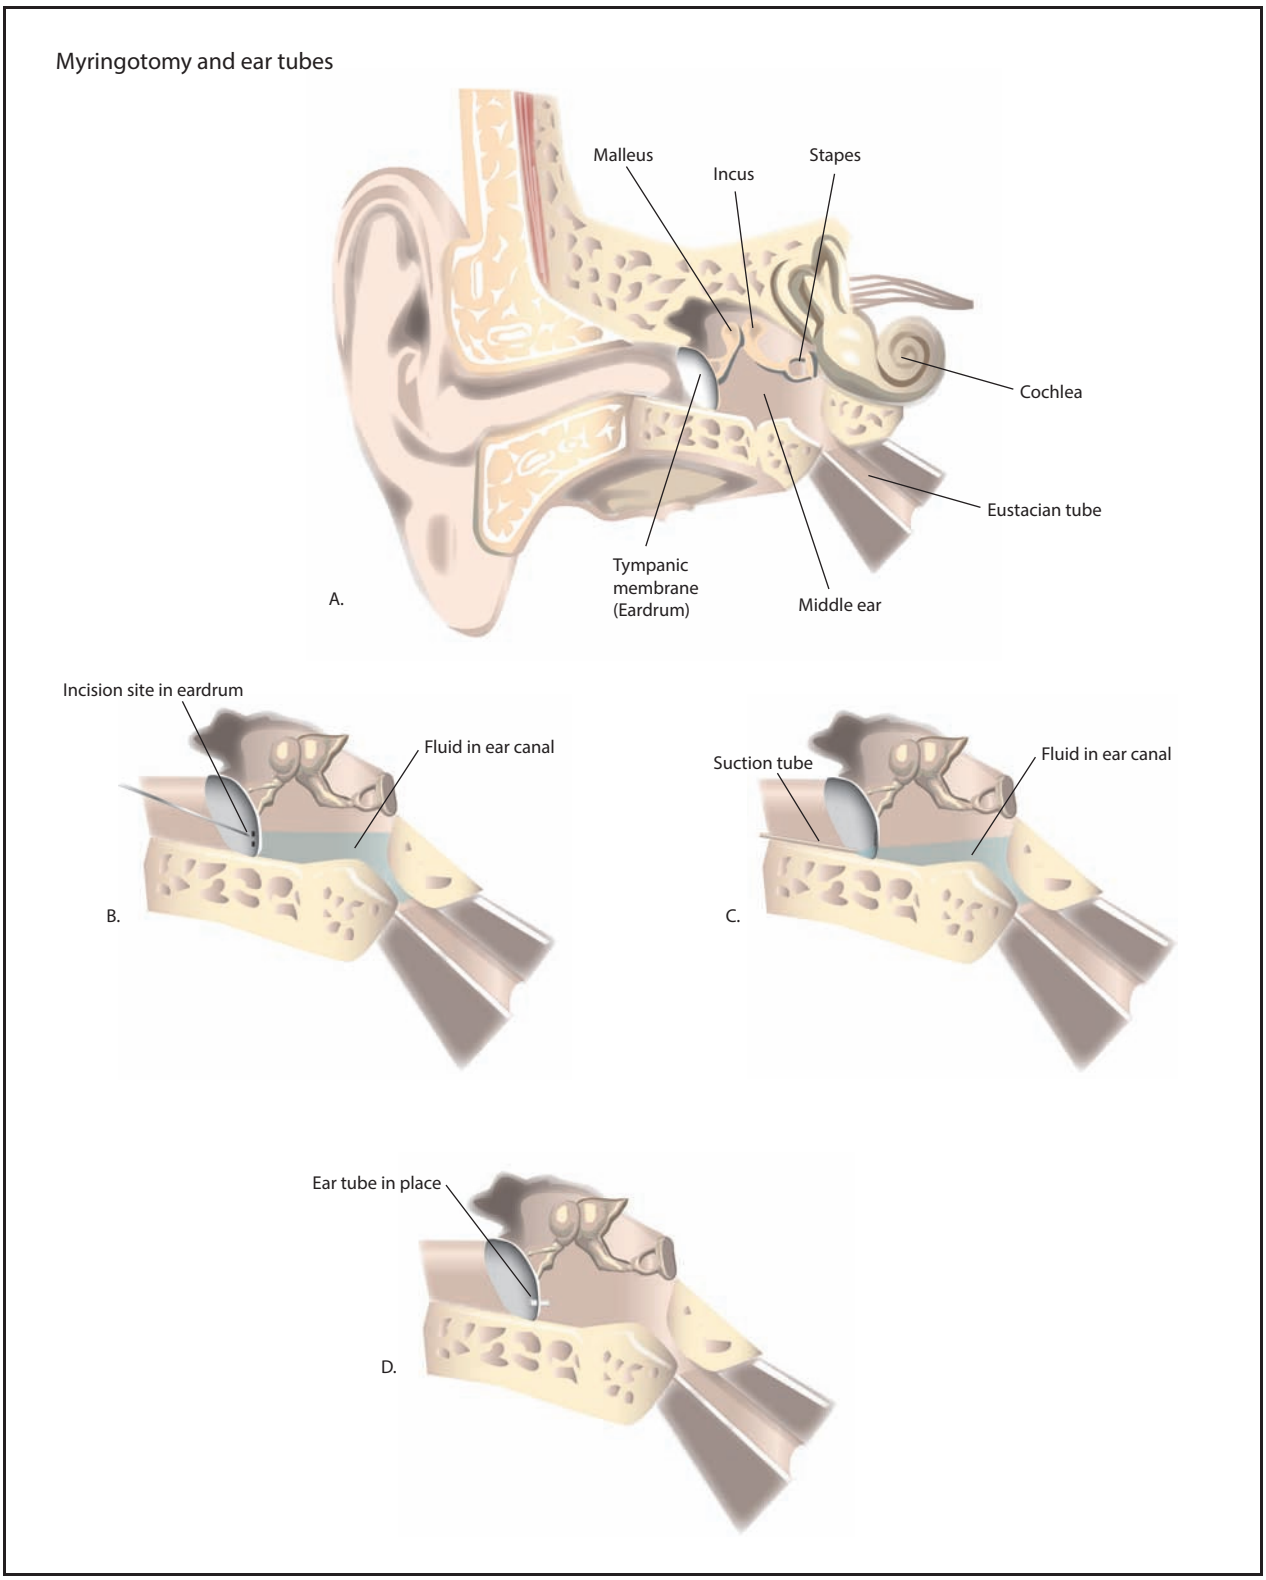
Myringotomy and ear tubes

Definition

Myringotomy is a surgical procedure in which a small incision is made in the eardrum (the tympanic membrane), usually in both ears. The English word is



During a myringotomy, an incision is made into the ear drum, or tympanic membrane (B). The fluid in the ear canal is suctioned out (C), and a small tube is put in place to allow future drainage in the event of an ear infection (D). *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

WWW.BOOKBAZ.IR

derived from *myringa,* modern Latin for drum membrane, and *tomē,* Greek for cutting. It is also called myringocentesis, tympanotomy, tympanostomy, or **paracentesis** of the tympanic membrane. Fluid in the middle ear can be drawn out through the incision.

Ear tubes, or tympanostomy tubes, are small tubes open at both ends that are inserted into the incisions in the eardrums during myringotomy. They come in various shapes and sizes and are made of plastic, metal, or both. They are left in place until they fall out by themselves or until they are removed by a doctor.

Demographics

In the United States, myringotomy and tube placement have become a mainstay of treatment for recurrent **otitis media** in children. More than 500,000 procedures are performed annually, making myringotomy the most common pediatric, ambulatory operation performed in the United States. Myringotomy in adults is a less common procedure than in children, primarily because adults benefit from certain changes in the anatomy of the middle ear that occur after childhood. In particular, the adult ear is less likely to accumulate fluid because the Eustachian tube, which connects the middle ear to the throat area, lies at about a 45–degree angle from the horizontal. This relatively steep angle means that the force of gravity helps to keep fluids from the throat containing disease organisms out of the middle ear. In children, however, the Eustachian tube is only about 10 degrees above the horizontal, which makes it relatively easy for disease organisms to migrate from the nose and throat into the inner ear. Myringotomies in adults are usually performed as a result of barotrauma, which is also known as pressure-related ear **pain** or barotitis media. Barotrauma refers to earache caused by unequal air pressure on the inside and outside of the eardrum. Adults with very narrow Eustachian tubes may experience barotrauma in relation to scuba diving, using elevators, or frequent flying. A myringotomy with tube insertion may be performed if the condition is not helped by **decongestants** or **antibiotics**.

Purpose

Myringotomy with the insertion of ear tubes is an optional treatment for inflammation of the middle ear with fluid collection (effusion) that lasts longer than three months (chronic otitis media with effusion) and does not respond to drug treatment. This condition is also called glue ear. Myringotomy is the recommended treatment if the condition lasts four to six months. Effusion refers to the collection of fluid that escapes from blood vessels or the lymphatic system. In this case, the effusion collects in the middle ear.

Initially, acute inflammation of the middle ear with effusion is treated with one or two courses of antibiotics. **Antihistamines** and decongestants have been used, but they have not been proven effective unless there is also hay **fever** or some other allergic inflammation that contributes to the problem. Myringotomy with or without the insertion of ear tubes is *not* recommended for initial treatment of otherwise healthy children with middle ear inflammation with effusion.

In about 10% of children, the effusion lasts for three months or longer, when the disease is considered chronic. In children with chronic disease, systemic **steroids** may help, but the evidence is not clear, and there are risks.

When medical treatment does not stop the effusion after three months in a child who is one to three years old, is otherwise healthy, and has **hearing loss** in both ears, myringotomy with insertion of ear tubes becomes an option. If the effusion lasts for four to six months, myringotomy with insertion of ear tubes is recommended.The purpose of myringotomy is to relieve symptoms, to restore hearing, to take a sample of the fluid to examine in the laboratory in order to identify any microorganisms present, or to insert ear tubes.

Ear tubes can be inserted into the incision during myringotomy and left there. The eardrum heals around them, securing them in place. They usually fall out on their own in six to 12 months or are removed by a doctor.While the tubes are in place, they keep the incision from closing, keeping a channel open between the middle ear and the outer ear. This allows fresh air to reach the middle ear, allowing fluid to drain out, and preventing pressure from building up in the middle ear. The patient's hearing returns to normal immediately and the risk of recurrence diminishes.

Most myringotomies in children are performed in children between one to two years of age. One Canadian study found that the number of myringotomies performed was 12.8 per thousand for children 11 months old or younger; 54.2 per thousand for children between 12 and 23 months old; and 11.1 per thousand for children between three and 15 years old. Sex and race do not appear to affect the number of myringotomies in any age group, although boys are reported to have a slightly higher rate of ear infections than girls.

KEY TERMS

Acute otitis media—Inflammation of the middle ear with signs of infection lasting less than three months.

Adenoids—Clusters of lymphoid tissue located in the upper throat above the roof of the mouth. Some doctors think that removal of the adenoids may lower the rate of recurrent otitis media in high-risk children.

Barotrauma—Ear pain caused by unequal air pressure on the inside and outside of the ear drum. Barotrauma, which is also called pressure-related ear pain or barotitis media, is the most common reason for myringotomies in adults.

Chronic otitis media—Inflammation of the middle ear with signs of infection lasting three months or longer.

Effusion—The escape of fluid from blood vessels or the lymphatic system and its collection in a cavity, in this case, the middle ear.

Eustachian tube—A canal that extends from the middle ear to the pharynx.

Insufflation—Blowing air into the ear as a test for the presence of fluid in the middle ear.

Middle ear—The cavity or space between the eardrum and the inner ear. It includes the eardrum, the three little bones (hammer, anvil, and stirrup) that transmit sound to the inner ear, and the Eustachian tube, which connects the inner ear to the nasopharynx (the back of the nose).

Otolaryngologist—A surgeon who specializes in treating disorders of the ears, nose, and throat.

Tympanic membrane—The eardrum. A thin disc of tissue that separates the outer ear from the middle ear.

Tympanostomy tube—Ear tube. A small tube made of metal or plastic that is inserted during myringotomy to ventilate the middle ear.

Description

When a conventional myringotomy is performed, the ear is washed, a small incision made in the eardrum, the fluid sucked out, a tube inserted, and the ear packed with cotton to control bleeding.

Recent developments include the use of medical **acupuncture** to control pain during the procedure, and the use of carbon dioxide lasers to perform the myringotomy itself. Laser-assisted myringotomy can be performed in a doctor's office with only a local anesthetic. It has several advantages over the older technique: it is less painful; less frightening to children; and minimizes the need for tube insertion because the hole in the eardrum produced by the laser remains open longer than an incision done with a scalpel.

Another technique to keep the incision in the eardrum open without the need for tube insertion is application of a medication called mitomycin C, which was originally developed to treat **bladder cancer**. The mitomycin prevents the incision from sealing over. However, this approach was still being studied.

There has also been an effort to design ear tubes that are easier to insert or to remove, and to design tubes that stay in place longer. Ear tubes come in various shapes and sizes designed to meet the needs of each specific patient.

Diagnosis/Preparation

The diagnosis of otitis media is based on the doctor's visual examination of the patient's ear and the patient's symptoms. Patients with otitis media complain of earache and usually have a fever, sometimes as high as 105°F (40.5°C). There may or may not be loss of hearing. Small children may have **nausea and vomiting**. When the doctor looks in the ear with an otoscope, the patient's eardrum will look swollen and may bulge outward. The doctor can evaluate the presence of fluid in the middle ear either by blowing air into the ear, known as insufflation, or by tympanometry, which is an indirect measurement of the mobility of the eardrum. If the eardrum has already ruptured, there may be a watery, bloody, or pus-streaked discharge.

Fluid removed from the ear can be taken to a laboratory for culture. The most common bacteria that cause otitis media are *Pneumococcus*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Some cases are caused by viruses, particularly respiratory syncytial virus (RSV).

A child scheduled for a myringotomy should not have food or water for four to six hours before **anesthesia**. Antibiotics are usually not needed.

If local anesthesia is used, a cream containing lidocaine and prilocaine is applied to the ear canal about 30 minutes before the myringotomy. If medical acupuncture is used for pain control, the acupuncture begins about 40 minutes before surgery and is continued during the procedure.

WWW.BOOKBAZ.IR

Aftercare

The use of antimicrobial drops is controversial. Water should be kept out of the ear canal until the eardrum is intact. A doctor should be notified if the tubes fall out.

Risks

The risks include:

- cutting the outer ear
- formation at the myringotomy site of granular nodes due to inflammation
- formation of a mass of skin cells and cholesterol in the middle ear that can grow and damage surrounding bone (cholesteatoma)
- permanent perforation of the eardrum

It is also possible that the incision will not heal properly, leaving a permanent hole in the eardrum. This result can cause some hearing loss and increases the risk of infection.

The ear tube may move inward and get trapped in the middle ear, rather than move out into the external ear, where it either falls out on its own or can be retrieved by a doctor. The exact incidence of tubes moving inward is not known, but it could increase the risk of further episodes of middle-ear inflammation, inflammation of the eardrum or the part of the skull directly behind the ear, formation of a mass in the middle ear, or infection due to the presence of a foreign body.

The surgery may not be a permanent cure. As many as 30% of children undergoing myringotomy with insertion of ear tubes need to undergo another procedure within five years.

Other risks include those associated with sedatives or general anesthesia. Some patients may prefer acupuncture for pain control in order to minimize these risks.

An additional element of postoperative care is the recommendation of many doctors that the child use ear plugs to keep water out of the ear during bathing or swimming to reduce the risk of infection and discharge.

Results

Parents often report that children talk better, hear better, are less irritable, sleep better, and behave better after myringotomy with the insertion of ear tubes. Normal results in adults include relief of ear pain and ability to resume flying or deep-sea diving without barotrauma.

Morbidity and mortality rates

Morbidity following myringotomy usually takes the form of either otorrhea, which is a persistent discharge from the ear or changes in the size or texture of the eardrum. The risk of otorrhea is about 13%. If the procedure is repeated, the eardrum may shrink, retract, or become flaccid. The eardrum may also develop an area of hardened tissue. This condition is known as tympanosclerosis. The risk of hardening is 51%; its effects on hearing are not known, but they appear to be insignificant.

In 2008, it was reported that morbidity following myringotomy in the United States is highest among children from families of low socioeconomic status. The study found that children from poor urban families had more episodes of otorrhea following tube insertion then children from suburban families. In addition, the episodes of otorrhea in the urban children lasted longer.

Mortality rates are extremely low; case studies of fatalities following myringotomy are rare in the medical literature, and most involve adults.

Alternatives

Preventive measures

There are several lifestyle issues related to high rates of middle ear infection. One of the most serious is parental **smoking**. One study of the effects of passive smoking on children's health estimated that as many as 165,000 of the myringotomies performed each year on American children are related to the use of tobacco in the household.

Studies have shown that children in daycare have a higher risk of chronic ear infection and, therefore, a higher risk of needing myringotomy.

A third factor that affects a child's risk of recurrent middle ear infection is **breastfeeding**. Toddlers who were breastfed as infants for at least four months have a lower risk of ear infection than those who were bottlefed.

Other surgical approaches

Because the adenoids may harbor infection, when myringotomy and tube placement fails, **adenoidectomy** may be performed in order to resolve chronic otitis media.

Alternative medicine

According to Dr. Kenneth Pelletier, former director of the program in complementary and alternative

medicine at Stanford University, there is some evidence that homeopathic treatment is effective in reducing the pain of otitis media in children and lowering the risk of recurrence.

Myxoma

Definition

A myxoma is a rare, usually noncancerous, primary tumor (a new growth of tissue) of the heart. It is the most common of all benign heart tumors.

Description

Myxoma is an intracardiac tumor; it is found inside the heart. Seventy-five percent of all myxomas are found in the left atrium, and almost all other myxomas are found in the right atrium. It is very rare for a myxoma to be found in either of the ventricles. The tumor takes one of two general shapes: a round, firm mass, or an irregular shaped, soft, gelatinous mass. These tumors are attached to the endocardium, the inside lining of the heart. The cells that make up the tumor are spindle-shaped cells and are embedded in a matrix rich in mucopolysaccharides (a group of carbohydrates). Myxomas may contain **calcium**, which shows up on x rays. The tumor gets its blood supply from capillaries that bring blood from the heart to the tumor. Thrombi (**blood clots**) may be attached to the outside of the myxoma.

There are three major syndromes linked to myxomas: embolic events, obstruction of blood flow, and constitutional syndromes. Embolic events happen when fragments of the tumor, or the thrombi attached to the outside of the tumor, are released and enter the blood stream. Gelatinous myxomas are more likely to embolize than the more firm form of this tumor.

Myxomas may also obstruct blood flow in the heart, usually at a heart valve. The mitral valve is the heart valve most commonly affected. Blood flow restrictions can lead to pulmonary congestion and heart valve disease. Embolization can lead to severe consequences. In cases of left atrial myxoma, 40–50% of patients experience embolization. Emboli usually end up in the brain, kidneys, and extremities.

The third syndrome linked to myxomas are called constitutional syndromes, nonspecific symptoms caused by the myxoma.

Causes and symptoms

There is no known causative agent for myxoma. The main symptoms, if any, produced by myxoma are generic and not specific. These include **fever**, weight loss, anemia, elevated white blood cell (WBC) count, decreased **platelet count**, and Raynaud's phenomenon. Most patients with myxoma are between 30–60 years of age.

WWW.BOOKBAZ.IR

KEY TERMS

Embolus—A piece of tissue, blood clot, etc., that travels through the blood system and can lodge in smaller blood vessels anywhere in the body.

Metastasis—The spread of a cancer or infectious agent from the site of origin to other areas of the body.

Raynaud's phenomenon—Intermittant ischemia (deficient blood flow) of the fingers or toes, sometimes also affecting the ears and nose.

Diagnosis

Diagnosis is made following a suspicion that a myxoma might be present, and can usually be confirmed by echocardiogram

Treatment

Surgery is used to remove the tumor. Myxomas can regrow if they are not completely removed. The survival rate for this operation is excellent.

Prognosis

Successful removal of the tumor rids the patient of this disease. Emboli from a myxoma may survive in other areas of the body. However, there is no evidence that myxoma is truly metastatic (able to transfer disease from one area to another), causing tumors in other areas of the body.

Nail fungus

Definition

Nail fungus is an infection of either the toenail or fingernail that is caused by an organism called a fungus. Medical terms for this condition are *onychomycosis* and *tinea unguium*. Statistics indicate that nail fungus affects 3 to 35 million Americans, and occurs more often as people age.

Description

Fungus (the plural is fungi) is a microorganism that is sometimes helpful to the human body and sometimes harmful. Because fungi can survive on dead tissue—hair, nails, and other outer layers of skin are all dead tissue—they can thrive and cause infection in those areas, especially the nails. Toenails are more susceptible than fingernails. The infection often occurs following other **fungal infections** such as athlete's foot. The greater occurrence in toenails most likely is due to the hospitable environment created by shoes that provide a dark, closed-in atmosphere where fungus gets a chance to grow, especially for people who tend to perspire heavily. An injury or **trauma** to a nail can also increase the chance of developing nail fungus.

Demographics

Because nail fungus is most likely to afflict those individuals with a weakened immune system, vulnerable to infections of all kinds, it is also more likely to occur in the older adult population, especially those who are diabetic. Diminished blood circulation—a factor in depriving optimal oxygen levels for healing—is often apparent in older adults and people who have diabetes, another issue that makes this population more susceptible to infection, especially in the extremities such as feet and hands. Women are likely to have nail infections probably due to the use of fingernail polish, but men seem to have a higher incidence of nail fungus. Though not proven, some professionals believe nail fungus development may be partly hereditary because resistance to fungal infection has a genetic component.

Causes and symptoms

The primary cause of nail fungus is the growth of microscopic organisms that thrive in dark, moist areas. The type that causes nail fungus belongs to a group known as *dermatophytes*. Yeasts and molds are also known causes of nail fungus infections. These organisms thrive in places such as swimming pools or showers, and people are vulnerable to them if they have any small, invisible cut in the skin or through the separation between the nail and the nail bed. At these sites nail fungus finds a welcome environment. Moreover, shoes provide dark, warm, and moist environments for nail fungus, which fares worse when exposed to light and air.

Symptoms of nail fungus might at first be subtle. The nail is slightly brittle, and a person may barely notice the change. Staying alert to less subtle changes, however, is important in treating the problem. According to *Medline Plus,* an Internet service of the U.S. National Library of Medicine and the National Institutes of Health, the signs to look for, in addition to brittleness, are: discoloration of the nail; a loss of luster or shine; a thickening of the nail; distortion of the nail shape; crumbling of the nail; debris getting trapped under the nail causing the nail to appear dark, or darker than usual; and, a loosening of the nail from the nail bed.

Diagnosis

Once the symptoms of nail fungus appear, a physician or medical professional will scrape the nail to abstract a culture for microscopic examination to

WWW.BOOKBAZ.IR

Nail fungus. *(© lekcej/Shutterstock.com)*

confirm that it is a fungus and to determine what type it is so the doctor can prescribe the most effective medication. Careful observation is crucial to noticing the changes that might indicate a person has nail fungus and to get it treated as soon as possible to avoid permanent damage to nails or secondary skin infections that might occur due to the nail fungus. If not treated properly, nail fungus infections will recur in the nails or in other parts of the body.

Treatment

To treat nail fungus effectively, anti-fungal medicines that are available only by prescription are used. These medications include itraconazole (Sporanox) and terbinafine (Lamisil). These medications are taken orally and clear up the infection in approximately 50% of individuals. These medicines assure the growth of new nails will be free from infection as they slowly replace the old, infected part of the nail. The medicines are taken typically for six to 12 weeks. The nail could take four months or longer to grow back completely and be rid of the infection. If the physician decides it is best to remove the nail, medicine is still prescribed, and it can take up to a year for the nail to grow back.

Another treatment involves an anti-fungal nail polish known as ciclopirox (Penlac), available only by prescription, which is painted on the nail and surrounding skin once a day. In seven days, the piled-on layers of the polish are cleaned with alcohol, and then a new series of applications is given for another seven days. This treatment method may take as much as a year and has been shown to be successful in less than 10% of cases.

Over-the-counter antifungal cream and ointments are generally not effective in ridding the system of the fungus. A physician might suggest that those containing urea might be used in conjunction with oral medication. The urea helps to speed absorption in the nail and, thus, increase the speed of eliminating the infection.

In the case of a severe or severely painful infection, the physician may recommend removing the nail. Oral medication is prescribed while the new nail grows back in order to ensure the fungus is removed from the person's system. The nail can take a year to grow back though the rate of growth varies among individuals.

Newer laser treatment has shown success in fighting nail fungus. A physician shines a special laser at the nail, which vaporizes and destroys the organisms causing a chronic fungal infection. The treatment often is performed in a podiatrist's office and takes 30 minutes to an hour.

Some individuals rely on home remedies such as vinegar foot or hand baths, for instance. According to information provided by the Mayo Clinic, some studies have shown that these kinds of treatment do inhibit the growth of certain bacteria. Soaking affected feet or hands for 15 to 20 minutes in a mixture of one part vinegar to two parts warm water is considered the most effective formula. It is essential to dry the affected area properly when the bath is completed. Another home remedy employs commercially available mentholated rub ointments on nail fungus. No controlled studies have been recently conducted to ascertain the effectiveness of this treatment, though anecdotal evidence is positive. Such alternative procedures are best discussed with a physician or medical professional before using.

Diabetics should treat nail fungus immediately; doing so helps to keep the infection from spreading. Since diabetics have impaired oxygen flow and thus have difficulty in healing **wounds** or sores, they are more vulnerable to the life-threatening consequences of such infections. **Amputation** of infected limbs can be necessary in order to stop the infection from spreading to other areas of the body.

Nutrition/dietetic concerns

As with any infection that attacks vulnerable immune systems, a healthy diet and regular **exercise** are essential in decreasing the possibility that a person will be susceptible to infection. When taking prescribed medication, all precaution and advisories should be heeded if there are any side effects. People who have diabetes should maintain

optimum dietary control in order to promote the desired healing.

Prognosis

Treating nail fungus successfully involves appropriate diagnosis and medication, along with appropriate precaution to keep it from spreading to other nails. The outlook for curing nail fungus is positive when individuals follow a physician's prescriptions, but complete recovery may take months. Nail fungus can recur in the same nail or in other nails. If certain precautions are taken, the possibility of recurrence is minimized. Even with proper care and treatment, recurrence of nail fungus is not rare.

Prevention

Older adults, especially those who have diabetes, can help prevent nail fungus or its recurrence by following certain guidelines. Recommendations include good hygiene for both hands and feet as the first line of defense. Individuals ought to keep nails short, dry, and clean; wear appropriate socks (synthetic materials can keep feet dryer than cotton or wool); use an anti-fungal spray or foot powder for feet and inside the shoes; wear rubber gloves to help protect hands when in and out of water excessively; not trim or pick the skin around the nails that might expose the nails and skin to more germs; not walk barefoot in public places such as around pools or in showers or locker rooms and expose feet to germs; check manicure and pedicure salons carefully to ensure proper sterilization techniques of instruments; not use artificial nails or nail polish that might mask problems or infections and trap moisture that can increase infection risk; and wash hands carefully after touching an infected nail so that the infection does not get a chance to spread. Finally, it is prudent to take measures to maintain a healthy immune system.

Caregiver concerns

Nail fungus can spread further on the infected person and can spread to the caregiver if hygienic precautions are not taken. Individuals who help bathe or care for an affected person should were gloves. They should also handle the affected areas gently as they can be quite sore. Caregivers need to confirm that medications are taken as prescribed. Caregivers and others may offer transportation of the affected person to a podiatrist or senior center where foot and nail care services are offered.

Nail fungus symptoms

- brittleness
- discoloration
- thickening
- debris under the nail
- distortion of nail shape
- nail becoming detached or loosening

Nail infections *see* **Onychomycosis**

Nail-patella syndrome

Definition

Nail-patella syndrome, is a genetic disease of the connective tissue that produces defects in the fingernails, knee caps, and kidneys.

Description

Nail-patella syndrome is also known as Fong disease, hereditary oncho osteodysplasia (HOOD), iliac

WWW.BOOKBAZ.IR

horn disease, and Turner-Kieser syndrome. Patients who have nail-patella syndrome may show a variety of physical defects. The hallmark features of this syndrome are poorly developed fingernails, toenails, and patellae (kneecaps). Other common abnormalities include elbow deformities, abnormally shaped pelvis bone (hip bone), and kidney (renal) disease.

Less common medical findings include defects of the upper lip, the roof of the mouth, and unusual skeletal abnormalities. Skeletal abnormalities may include poorly developed scapulae (shoulder blades), sideways-bent fingers (clinodactyly), **clubfoot**, **scoliosis**, and unusual neck bones. There are also other effects, such as thickening of the basement membrane in the skin and of the tiny clusters of capillaries (glomeruli) in the kidney. Scientists have recognized an association between nail-patella syndrome and **colon cancer**. Nail-patella syndrome is associated with open-angle **glaucoma**, which, if untreated, may lead to blindness. Patients may also have **cataracts**, drooping eyelids (**ptosis**), or corneal problems such as glaucoma.

People with nail-patella syndrome may display only a few or many of the recognized signs of this disease. Symptoms vary widely from person to person. Signs even vary within a single family with multiple affected members.

The incidence of nail-patella syndrome is approximately one in 50,000 births. This disorder affects males and females equally. It is found throughout the world and occurs in all ethnic groups. The strongest risk factor for nail-patella syndrome is a family history of the disease.

Causes and symptoms

Nail-patella syndrome has been recognized as an inherited disorder for more than 100 years. It is caused by mutations in a gene known as LIM homeobox transcription factor 1-beta (LMX1B), located on the long arm of chromosome 9.

The LMX1B gene codes for a protein that is important in organizing embryonic limb development. Mutations in this gene have been detected in many unrelated people with nail-patella syndrome. Scientists have also been able to interrupt this gene in mice to produce defects similar to those seen in human nail-patella syndrome.

Nail-patella syndrome is inherited in an autosomal dominant manner. This means that possession of only one copy of the defective gene is enough to cause disease. When a parent has nail-patella syndrome each of their children has a 50% chance of inheriting the disease-causing mutation.

A new mutation causing nail-patella syndrome can also occur, resulting in disease in a person with no family history. This is called a sporadic occurrence and accounts for approximately 20% of cases of nail-patella syndrome. The children of a person with sporadic nail-patella syndrome are also at a 50% risk of developing signs of the disorder.

Medical signs of nail-patella syndrome vary widely between patients. Some patients with this disorder do not display symptoms. These patients are discovered to have the nail-patella syndrome only when genetic studies trace their family history. Scientists are now working to learn what causes different people to display such different symptoms of nail-patella syndrome.

The most obvious sign associated with nail-patella syndrome is absent, poorly developed, or unusual fingernails. Fingernail abnormalities are found in more than 80% of patients with this disorder. Abnormalities may be found in one or more fingernails. Only rarely are all fingernails affected. This disease most commonly affects the fingernails of the thumbs and index fingers. The pinky fingernail is least likely to be affected. Fingernails may be small and concave with pitting, ridges, splits, and/or discoloration. Toenails are less often affected. The lunulae, or light-colored crescent moons, at the base of the fingernail bed next to the cuticle are sometimes triangularly-shaped in people with nail-patella syndrome.

Kneecap abnormalities are the second most common sign associated with this disorder. Either or both kneecaps may be missing or poorly formed. If present, kneecaps are likely to be dislocated. The knees of people with nail-patella syndrome may have a square appearance. Besides the kneecap, other support structures including bones, ligaments, and tendons may also be malformed. These support structures stabilize the knee, therefore patients with some leg malformations may have difficulty in walking.

The hip bones of approximately 80% of patients with nail-patella syndrome have unusual bony projections called posterior iliac horns. These bony projections, or spurs, are internal and not obvious unless they are detected on x ray. This unusual pelvic anatomy is not associated with any other disease.

Kidney disease is present in at least 30% of people with nail-patella syndrome. Biopsy shows lesions that resemble those of inflammation of the clusters of capillaries in the kidneys (**glomerulonephritis**), but without any infection present. Kidney failure is the most dangerous consequence of nail-patella syndrome. It occurs in about 30% of patients who have kidney

involvement. An early sign of kidney involvement is the presence of protein or blood in the urine (chronic, benign proteinuria and hematuria.) Kidney involvement is progressive, so early diagnosis and treatment of renal disease is important. Kidney disease has been reported in children with nail-patella syndrome, but renal involvement more commonly develops during adulthood.

Various skeletal symptoms may occur. Patients with nail-patella syndrome may not be able to fully straighten their arms at the elbow. This may create a webbed appearance at the elbow joint. Patients may have sideways-bent fingers, poorly developed shoulder blades, clubfoot, hip dislocation, unusual neck bones, or scoliosis.

Eye problems may be present and vary from person to person. Nail-patella syndrome is associated with open angle glaucoma. Open angle glaucoma is caused by fluid blocked into the front chamber of the eye. This blocked fluid builds increasing pressure into the eye. If untreated, this increased pressure may lead to permanent damage of the optic nerve and irreversible blindness. Some patients with nail-patella syndrome have ptosis, or drooping eyelids. Nail-patella syndrome has also been associated with abnormalities of the cornea, cataracts, and **astigmatism**. Additionally, the irises of the eye may be multicolored, possibly displaying a clover-shaped pattern of color.

Diagnosis

Genetic testing for nail-patella syndrome is available only through research institutions that are working to further characterize this disorder. Genetic testing cannot predict which signs of the disease will develop, nor can genetic testing predict the severity of disease symptoms. Improved genetic testing for nail-patella syndrome is anticipated in the future.

Diagnosis of this disease is most often made on visual medical clues such as the characteristic abnormalities of the fingernails and kneecaps. Diagnosis is confirmed by x-ray images of the affected bones and, when indicated, **kidney biopsy**. The bony pelvic spurs found in 80% of patients with nail-patella syndrome are not associated with any other disease.

Prenatal diagnosis for nail-patella syndrome by third-trimester **ultrasound** was documented in 1998. Prenatal diagnosis via genetic testing of cells obtained by **chorionic villus sampling** was reported the same year. Prenatal genetic testing for nail-patella syndrome is not yet widely available. Controversy surrounds the use of prenatal testing for such a variable disorder. Prenatal testing cannot predict the extent of an individual's disease.

KEY TERMS

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Glomeruli—Tiny clusters of capillaries in the kidney.

Hematuria—The presence of blood in the urine.

Patella—The kneecap.

Proteinuria—Excess protein in the urine.

Treatment

Treatment is usually not necessary. Treatment, when required, depends on each patient's specific symptoms. Severe kidney disease is treated with dialysis or a kidney transplant. Patients receiving kidney transplants do not develop nail-patella type renal complications in their new kidney.

A wheelchair may be required if walking becomes painful due to bone, tendon, ligament, or muscle defects. **Orthopedic surgery** may be necessary for congenital clubfoot deformity. Manipulation or surgery may be required to correct hip dislocation. Cataracts are also surgically treated. Medical treatment at early signs of glaucoma prevents progression of the disease to blindness.

Genetic counseling is offered to persons who have the disease. Parents with this disease have a 50% chance of passing it to each of their children. Current genetic testing technology cannot predict the severity or scope of an individual's symptoms.

Because many possible manifestations of nail-patella syndrome exist, patients are advised to pursue extra medical care including regular **urinalysis** and special eye exams. Children with nail-patella syndrome should be screened for scoliosis.

Prognosis

Survival among patients with nail-patella syndrome is not decreased unless a they exhibit renal

WWW.BOOKBAZ.IR

complications. It is estimated that 8% of individuals with nail-patella syndrome who come to medical attention eventually die of kidney disease.

The physiology of the human fingernail. The most common causes of nail disorders include trauma, infections, exposure to harsh detergents, hot water and other irritants, systemic diseases and disorders, and allergic reactions. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Nail removal

Definition

Nail removal is a form of treatment that is sometimes necessary following traumatic injuries or recurrent infections in the area of the nail. There are nonsurgical as well as surgical methods of nail removal.

Purpose

Nails are removed only when necessary to allow the skin beneath the nail (the nail bed) to heal or in some cases, to remove a nail that has been partially pulled out in an accident. In the case of toenails, it is occasionally necessary to remove the nail of the large toe due to a chronic condition caused by badly fitted shoes. In general, however, doctors prefer to try other forms of treatment before removing the nail. Depending on the cause, nail disorders are usually treated through: the use of oral medications; medicated gels or creams applied directly to the skin around the nail; the avoidance of substances that irritate the nail folds; surgical lancing of abscesses around the nail; or the injection of **corticosteroids** under the nail fold.

The most common causes of nail disorders include:

- Trauma. The nails can be damaged by nail biting, using the fingernails as tools, and incorrect use of nail files and manicure scissors as well as by accidents and sports injuries.
- Infections. These include fungal infections under the nails, bacterial infections of cuts or breaks in the nail folds, or infections of the nails themselves caused by the fungus *Candida albicans*. Inflammation of the nail folds is called paronychia.
- Exposure to harsh detergents, industrial chemicals, hot water, and other irritants. People who work as dishwashers are especially vulnerable to separation of the nail itself from the nail bed (onycholysis).
- Systemic diseases and disorders. These include psoriasis, anemia, and certain congenital disorders.
- Allergic reactions to nail polish, polish remover, or the glue used to attach false nails.

Precautions

In the case of infections, it is necessary to distinguish between fungal, bacterial, and candidal infections before removing the nail. Cultures can usually be obtained from pus or tissue fluid from the affected nail.

Description

Surgical nail removal

If necessary, the surgeon can remove the nail at its base with an instrument called a needlepoint scalpel. In a few cases, the nail may need to be pulled out (avulsed) from its matrix.

Nonsurgical nail removal

Nails can be removed by applying a mixture of 40% urea, 20% anhydrous lanolin, 5% white wax, 25% white petroleum jelly, and silica gel type H.

KEY TERMS

Avulse—To pull or tear away forcibly. In some cases, a surgeon must remove a nail by avulsing it from its matrix.

Matrix—The tissue at the base of the nail, from which the nail grows.

Nail bed—The layer of tissue underneath the nail.

Onycholysis—The separation of a nail from its underlying bed. Onycholysis is a common symptom of candidal infections of the nail or of exposure to harsh chemicals and detergents.

Paronychia—Inflammation of the folds of skin that surround a nail.

Preparation

For nonsurgical nail removal, the nail fold is treated with tincture of benzoin and covered with adhesive tape. The nail itself is thickly coated with the urea mixture, followed by a layer of plastic film and adhesive tape. The mixture is left on the nail for five to 10 days, after which the nail itself can be removed.

Aftercare

Aftercare of surgical removal is similar to the care of any minor surgical procedure. Aftercare of the urea paste method includes applying medication for the specific infection that is being treated.

Results

Normal results include the successful removal of the infected or damaged nail.

Risks

Risks from either procedure are minimal.

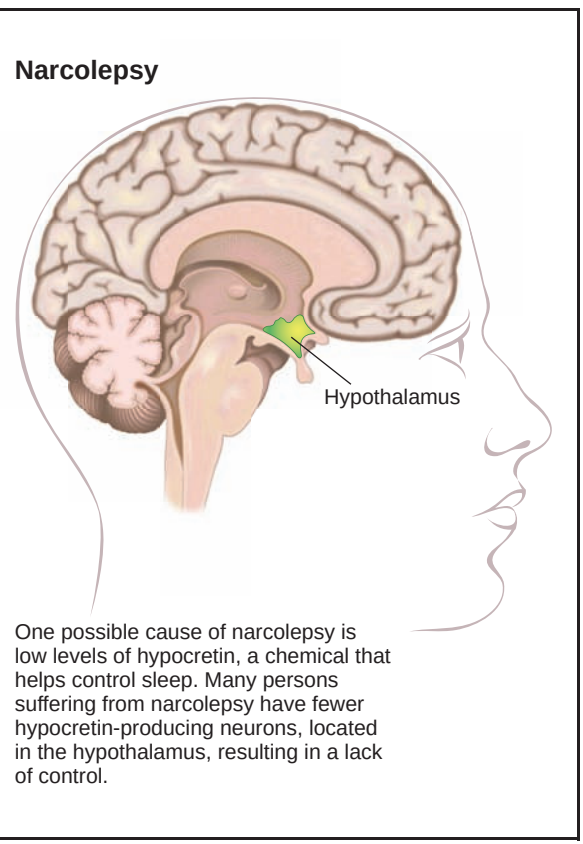
Narcolepsy

Definition

Narcolepsy is a neurological disorder marked by excessive daytime sleepiness, uncontrollable sleep attacks, and cataplexy (a sudden loss of muscle tone, usually lasting up to half an hour).

Demographics

According to the National Institute for Neurological Disorders and **Stroke** (NINDS), narcolepsy is an underrecognized and underdiagnosed condition in the United States. The exact prevalence is not known, but it is estimated to affect about one in every 2,000 Americans. The disorder occurs worldwide in every racial and ethnic group, affecting males and females equally. However, prevalence varies among populations. For example, narcolepsy is less prevalent in Israel (about one per 500,000) but considerably more prevalent in Japan (about one per 600).



One possible cause of narcolepsy is low levels of hypocretin, a chemical that helps control sleep. Many persons suffering from narcolepsy have fewer hypocretin-producing neurons, located in the hypothalamus, resulting in a lack of control.

WWW.BOOKBAZ.IR

Description

Narcolepsy is the second-leading cause of excessive daytime sleepiness (after obstructive **sleep apnea**). Persistent sleepiness and sleep attacks are the hallmarks of this condition. The sleepiness has been compared to the feeling of trying to stay awake after not sleeping for two or three days.

People with narcolepsy fall asleep suddenly—anywhere, at any time, maybe even in the middle of a conversation. These sleep attacks can last from a few seconds to more than an hour. Depending on where they occur, they may be mildly inconvenient or even dangerous to the individual. Some people continue to function outwardly during the sleep episodes, such as talking or putting things away. But when they wake up, they have no memory of the event.

Narcolepsy is related to the deep, dreaming part of sleep known as rapid eye movement (REM) sleep. Normally when people fall asleep, they experience 90 minutes of non–REM sleep, which is then followed by REM sleep. People with narcolepsy, however, enter REM sleep immediately. In addition, REM sleep occurs inappropriately throughout the day.

Risk factors

According to the NINDS, close relatives of people with narcolepsy have a statistically higher risk of developing the condition than do members of the general population.

Causes and symptoms

Narcolepsy sometimes runs in families, but most cases are sporadic, meaning that the disorder occurs independently in individuals without strong evidence of being inherited. Some researchers therefore believe that the inheritance of narcolepsy is similar to that of **heart disease**. In heart disease, several genes play a role in being susceptible to the disorder, but it usually does not develop without an environmental trigger of some sort. Other factors, such as infection, immune system deficiencies, **trauma**, hormonal changes, and **stress** may also play a role in the development of the disease.

The immediate cause of narcolepsy remains unknown but as of 2014, medical researchers have made considerable progress in understanding the disorder and in identifying genes strongly associated with it. Abnormalities in various parts of the brain involved in regulating REM sleep were also discovered. Narcolepsy is now known to have one of the tightest associations with a specific form, or allele, of the HLA gene family. The HLA gene family provides instructions for making a group of related proteins known as the human leukocyte antigen (HLA) complex. The HLA complex helps the immune system distinguish the body's own proteins from proteins made by foreign invaders such as viruses and bacteria. From 88% to 98% of patients affected by narcolepsy have been shown to be positive for the allele known as HLA DQB1*0602. This allele strongly increases the susceptibility for cataplexy, although 41% of patients without cataplexy are carriers. DRB1 and DQB1 genes have been sequenced in narcolepsy patients but no mutation has been identified. This suggests that these genes strongly confer susceptibility to narcolepsy without their function being defective. It is accordingly believed that non–HLA genes may also be involved in susceptibility to narcolepsy.

While the symptoms of narcolepsy usually appear during the teens or 20s, the disease may not be diagnosed for many years. The most common major symptom is excessive daytime sleepiness (EDS), an overwhelming feeling of **fatigue**. After several months or years, cataplexy and other symptoms appear.

Cataplexy is the most dramatic symptom of narcolepsy. It affects 75% of people with the disorder. During attacks, the knees buckle and the neck muscles go slack. In extreme cases, the person may become paralyzed and fall to the floor. This loss of muscle tone is temporary, lasting from a few seconds to half an hour, but frightening. The attacks can occur at any time but are often triggered by strong emotions, such as anger, joy, or surprise.

Other symptoms of narcolepsy include:

- sleep attacks: short, uncontrollable sleep episodes throughout the day
- sleep paralysis: a frightening inability to move shortly after awakening or dozing off
- auditory or visual hallucinations: intense, sometimes terrifying experiences at the beginning or end of a sleep period
- disturbed nighttime sleep: tossing and turning, nightmares, and frequent awakenings during the night

Diagnosis

Examination

In most patients, narcolepsy is not diagnosed until 10 to 15 years after the first symptoms appear. This is because the disorder is not familiar to most of the general public. The disorder is suspected when a person reports both excessive daytime sleepiness and cataplexy. Diagnosis is established on the basis of a clinical examination and comprehensive medical history.

KEY TERMS

Cataplexy—A symptom of narcolepsy in which there is a sudden episode of muscle weakness triggered by emotions. The muscle weakness may cause the person's knees to buckle, or the head to drop. In severe cases, the patient may become paralyzed for a few seconds to minutes.

Excessive daytime sleepiness (EDS)—A persistent sense of mental cloudiness, a lack of energy, a depressed mood, or extreme state of exhaustion.

Hypnagogic hallucinations—Dream–like auditory or visual hallucinations that occur while falling asleep.

Hypothalamus—A part of the forebrain that controls heartbeat, body temperature, thirst, hunger, body temperature and pressure, blood sugar levels, and other functions.

Sleep paralysis—An abnormal episode of sleep in which the patient cannot move for a few minutes, usually occurring on falling asleep or waking up. Often found in patients with narcolepsy.

Tests

Laboratory tests are required to confirm a diagnosis. These may include an overnight polysomnogram—a test in which sleep is monitored with **electrocardiography**, video, and respiratory parameters. A multiple sleep latency test, which measures sleep latency (onset) and how quickly REM sleep occurs, may be used. People who have narcolepsy usually fall asleep in less than five minutes.

If a diagnosis is in question, a genetic blood test can reveal the existence of certain substances in people who have a tendency to develop narcolepsy. Positive test results suggest, but do not prove, the existence of narcolepsy.

Treatment

There is no cure for narcolepsy. It is not progressive, and it is not fatal, but it is chronic. The symptoms can be managed with medication or lifestyle adjustment.

Drugs

Amphetamine–like stimulant drugs are often prescribed to control drowsiness and EDS attacks. Patients who do not like taking high doses of stimulants may choose to take smaller doses and "manage" their lifestyles, such as by napping every couple of hours, to relieve daytime sleepiness. Antidepressants are often effective in treating symptoms of abnormal REM sleep. In 2002, the FDA approved Xyrem® (**sodium** oxybate or gamma hydroxybutyrate, also known as GHB) for treating people with narcolepsy who experience episodes of cataplexy.

Prognosis

Narcolepsy is not a degenerative disease, and patients do not develop other neurologic symptoms. However, narcolepsy can interfere with a person's ability to work, play, drive, and perform other daily activities. In severe cases, the disorder prevents people from living a normal life, leading to depression and a loss of independence.

Prevention

Narcolepsy cannot be prevented.

Narcotics

Definition

Narcotics include natural opioid drugs derived from the Asian poppy *Palaver somniferous* and semi-synthetic and synthetic substitutes. Opiate (narcotic) **analgesics** are prescribed for **pain** relief and are addictive drugs of abuse.

Classes of narcotics

Narcotics of natural origin
Codeine
Morphine
Opium
Thebaine

Semi-synthetic narcotics
Heroin
Hydrocodone
Hydromorphone
Oxycodone

Synthetic narcotics
Butorphanol
Dextropropoxyphene
Fentanyl
Meperidine
Pentazocine

Narcotics treatment drugs
Buprenorphine
LAAM
Methadone

SOURCE: U.S. Department of Justice, Drug Enforcement Administration, Drugs of Abuse. Available online at: http://www.justice.gov/dea/docs/drugs_of_abuse_2011.pdf (accessed September 9, 2014)

(Table by PreMediaGlobal. © Cengage Learning®.)

Purpose

Narcotics are the most effective drugs available for relieving pain. They also cause drowsiness or sleep and are used pre-operatively to relieve **anxiety** and as **anesthesia**. Other common uses are **cough** suppression and control of very severe **diarrhea**. Narcotics are used illegally for recreation and are widespread drugs of abuse.

Precautions

Narcotics are prescription drugs that should be taken only under the direction of a physician. They depress the central nervous system and, in large doses, can suppress breathing and cause **coma** and death. They should never be taken in combination with other drugs, such as alcohol, **barbiturates**, **antihistamines**, or **benzodiazepines** that also depress the central nervous system. Opioids are broken down by the liver, and people with liver damage may not detoxify them readily, which can lead to accidental overdose. Narcotics can cause lethargy and interfere with the ability to function normally. Studies have found that while opioids are helpful for pain relief if taken for less than three months, long-term use

does not improve daily functioning in patients with chronic pain.

The use and abuse of narcotics—such as morphine, oxycodone (Oxycontin), and fentanyl—have increased significantly in recent years, leading to an epidemic of **addiction** and accidental overdoses. The U.S. Center for Disease Control and Prevention (CDC) estimates that, as of 2014, more than 14,000 Americans were dying annually from narcotic overdoses—a fourfold increase from a decade ago. Prescription drugs contributed to half of those deaths—more than heroin and cocaine combined. More Americans now die from drug overdoses than from traffic accidents. Fatal narcotic overdoses among women increased by 400% between 1999 and 2013, especially among middle-aged women who are more likely than others to be prescribed narcotics for chronic pain. Furthermore, large numbers of Iraq and Afghanistan veterans suffer from both chronic pain and **post-traumatic stress disorder** (PTSD) and are prescribed narcotics that, in combination with PTSD, present increased risk for accidents, addiction, and overdose. In 2012, the Veterans Administration (VA) treated more than 50,000 vets for serious problems associated opioid use and abuse. Accidental drug overdoses, primarily from prescription opioids, were almost twice as common among VA-enrolled vets as in the overall population.

Description

Natural narcotics are derived directly from the sap of unripe seed pods of the opium poppy. Morphine and codeine are the most frequently prescribed natural narcotics, often in combination with non-narcotic analgesics. Heroin is an illegal, semi-synthetic narcotic. Completely synthetic narcotics include prescription drugs such as oxycodone and fentanyl and illegal "designer drugs." Some synthetic narcotics are hundreds of times more potent than natural narcotics.

Narcotics depress the central nervous system by binding with receptors to block the transmission of nerve impulses and pain perception. They can also slow or block muscle contractions to treat coughs or severe diarrhea caused by **cholera** or similar diseases.

Types of narcotics

Codeine is the most commonly prescribed narcotic. Since codeine concentrations in the opium poppy are low, most codeine is manufactured by chemical alteration of morphine sap. Codeine is combined with other non-narcotic painkillers such as **aspirin**, **acetaminophen** (Tylenol with Codeine), or non-steroidal anti-inflammatory drugs as tablets (most common) or liquids of various strengths. Codeine is also added to some cough syrups for controlling dry cough. It is occasionally used to control severe diarrhea. Codeine-containing pain medication requires a prescription in the United States. Low-dose codeine pain relievers are available without a prescription in Canada, but purchases are electronically recorded. The likelihood of physical or psychological dependence on codeine is much lower than for morphine.

- Morphine sulfate is a white powder that dissolves in water. It is administered as a tablet or by injection into a muscle or a vein (intravenously). Intravenous injection is effective almost immediately. Regular use of morphine has a high potential for dependence or addiction. If stopped abruptly, withdrawal symptoms can occur. Morphine is not a common street drug.
- Oxycodone is a synthetic narcotic painkiller, manufactured alone or in combination with aspirin, acetaminophen, or ibuprofen, in tablets of various strengths, including controlled-release formulas for continuous pain relief. Oxycodone is both a prescription drug and a street drug with high potential for abuse.
- Hydrocodone with acetaminophen (Vicodin) is another widely used synthetic narcotic with high potential for abuse,
- Hydromorphone (Dilaudid) is a narcotic synthesized from morphine. It is available in tablets or as an injectable solution for pain relief. It is one of the most common pain relievers prescribed for terminally ill patients.
- Meperidine (Demerol) is a narcotic that was developed for treating muscle spasms but is used primarily for pain relief. It is manufactured as tablets of varying strengths. A similar narcotic painkiller, propoxyphene, was removed from the market in 2010 because of its potential to cause life-threatening heart disturbances.
- Fentanyl is used to treat breakthrough pain in cancer patients who are taking regular doses of another narcotic. It is available as a lozenge, tablet, film, or patch.
- Heroin and opium are street narcotics processed from poppy plants. They result in immediate euphoria when smoked or injected. Opium can also be taken by mouth.
- Methadone is a synthetic narcotic used primarily as a substitute for heroin. It blocks heroin cravings and withdrawal symptoms without heroin's psychoactive effects.

WWW.BOOKBAZ.IR

Availability

Until the 1990s, narcotics were rarely prescribed because of their addictiveness. With the emergence of the palliative-care movement and increased recognition of the terrible suffering of cancer patients, physicians began prescribing narcotics more liberally—and for all types of pain. In particular, primary-care physicians began prescribing more narcotics because they have few other options for helping their patients: an estimated 100 million Americans suffer from chronic pain, but there are only about 4,000 board-certified pain specialists in the United States. Marketing of opioids by pharmaceutical companies has also become more aggressive, and some of the newer synthetic opioids were initially believed to be less addictive.

The CDC has come out strongly against the use of narcotics for common aches and pains, arguing that physicians are prescribing them too often, too soon, and for too long, thereby placing patients at risk for addiction and life-threatening complications. The CDC advises that narcotics be reserved for conditions such as severe cancer pain.

- A 2013 study found that more than 50% of non-surgical hospitalized patients in the United States were prescribed narcotics, often at very high doses, and more than half of them were discharged with narcotic prescriptions. There were large regional variations, with the highest number of prescriptions in the West and the lowest number in the Northeast.
- A 2013 study found that the use of aspirin, acetaminophen, and similar over-the-counter pain relievers for back pain fell from about 37% in 1999–2000 to 24.5% in 2009–2010, whereas the use of narcotics for back pain increased from 19% to 29%.
- An analysis by the *Los Angeles Times* found that almost half of the 3,700 deaths from drug overdoses in Southern California between 2006 and 2011 involved at least one prescription drug, primarily painkillers, often in combination with alcohol or other narcotics. Many of the victims were addicted to narcotics that had been originally prescribed for injuries.
- A 2014 study found that pregnant women were being prescribed narcotics in large numbers, primarily for back or abdominal pain. Opioid use in very early pregnancy doubles the infant's risk of neural tube defects. Prolonged use late in pregnancy can lead to addiction in infants, which appears to be on the increase.

Unfortunately, many people who are initially prescribed narcotics for pain relief become addicted and exaggerate the severity of their pain, seek out multiple prescriptions from different doctors, or turn to street narcotics, including heroin, which may be much less expensive that prescription narcotics. Street drugs are of unknown potency and may be contaminated with toxic chemicals or contain mixtures of drugs that can cause overdoses and other life-threatening reactions. As a result, there is an increased focus by the medical profession, licensing agencies, and state and federal enforcement on short- and long-term prescribing practices. Some states have enacted sweeping legislation to try and curb narcotics prescriptions. For example, Washington State has adopted new guidelines that have led to a decline in fatal overdoses. As of 2014, the U.S. Food and Drug Administration (FDA) was considering new controls on prescription and promotion of narcotics.

Nevertheless, according to the National Survey on Drug Use and Health, less than 20% of prescription painkiller use and abuse results from physicians' prescriptions. Furthermore, there remains concern that pain is often inadequately treated, particularly among the poor, the mentally ill, and the elderly.

Preparation

Patients should inform their physicians about all of their prescription and nonprescription drugs, supplements, and herbal remedies, since some of these may enhance the effects of narcotics.

Aftercare

Regular use of narcotics for an extended period can lead to tolerance, in which higher and higher doses are required to achieve the same level of pain control. Withdrawal symptoms may develop if a narcotic is stopped abruptly. These can include:

- anxiety
- irritability
- rapid breathing
- runny nose
- sweating
- vomiting and diarrhea
- confusion
- shaking
- lack of appetite

Tapering is the gradual decrease in the dose of a narcotic to prevent withdrawal symptoms and allow for the drug to be discontinued completely without unpleasant effects. Clonidine is a blood pressure medication that is sometimes used to treat opiate withdrawal. Buprenorphine and naxalone are used alone

KEY TERMS

Agonist—A drug that binds to a receptor, such as an opiate receptor, and has activity similar to the binding of the endogenous substance or opiate.

Antagonist—A drug that blocks the action of a substance, such as an opiate, by binding to its receptor.

Codeine—A morphine derivative that is found in opium or synthesized; it is milder than morphine and is prescribed for pain relief and coughs.

Fentanyl—A synthetic opioid narcotic pain reliever with effects similar to morphine but many times stronger.

Heroin—An illegal and highly addictive narcotic that is made from morphine and is widely abused for its euphoric effects.

Morphine—An addictive narcotic derived from opium and prescribed as a painkiller and sedative.

Naxalone—An opioid antagonist that is used to counteract narcotic overdoses and to treat narcotic addiction and withdrawal.

Opiate—A drug containing or derived from opium—such as codeine, morphine, or heroin—that alleviates pain and induces sleep.

Opioid—A synthetic drug, such as methadone, that has narcotic properties similar to opiates but is not derived from opium.

Oxycodone—A narcotic painkiller that is widely abused.

Tapering—Gradually reducing the amount of a drug if stopping it abruptly would cause unpleasant withdrawal symptoms.

Tolerance—The requirement for increasingly higher doses of a substance, such as a narcotic, to achieve the same effect.

Withdrawal—Unpleasant, sometimes life-threatening, physiological effects of discontinuing some drugs, such as narcotics, following prolonged regular use.

or in combination to treat opioid addiction and withdrawal symptoms. Buprenorphine is a partial opioid agonist-antagonist. Naxalone is an opioid antagonist that blocks and reverses the effects of narcotics. Emergency medical personnel often carry naxalone or other opioid antagonists to counteract narcotic overdoses. When given intravenously, naxalone is effective within one–two minutes.

Results

When used as prescribed, narcotics generally provide safe and effective pain relief and can control coughing and severe diarrhea. A short-term course of narcotics following a dental or medical procedure will not lead to tolerance or addiction, provided that the prescribing instructions are followed.

Risks

All narcotics have the potential to become psychologically and physically addictive, and tolerance, abuse, and dependence are growing problems among people from all walks of life. Of particular concern is the increase in teenage use of prescription narcotics and unintentional abuse, misuse, or adverse interactions with other medications among elderly people being treated for chronic pain.

Narcotic overdoses are a major risk. Although overdoses can be fatal, there are no maximum doses of narcotics since, unlike aspirin or acetaminophen, high amounts do not permanently damage organs. Therefore, physicians often increase the doses as tolerance develops.

Nasal culture *see* **Nasopharyngeal culture**

Nasal irrigation

Definition

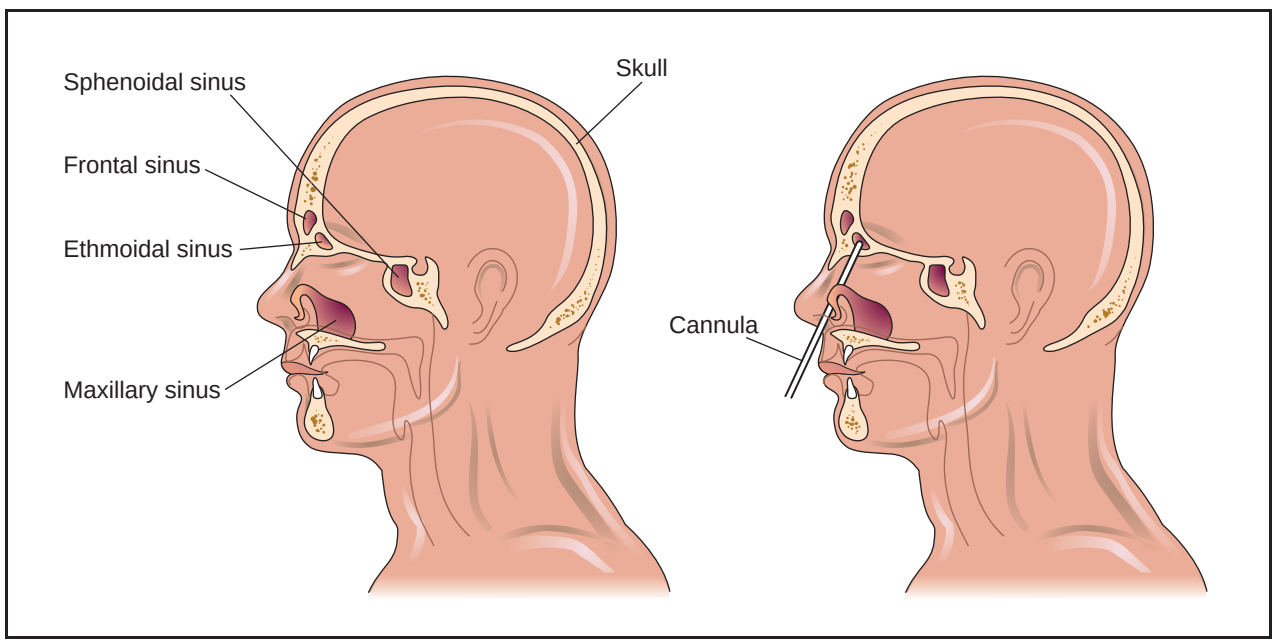
Nasal irrigation is the practice of flushing the nasal cavity with a sterile solution. The solution may contain **antibiotics** or steroid medications.

Purpose

Nasal irrigation is used to clear infected sinuses or may be performed after surgery to the nose region. It may be performed by adding antibiotics to the solution to treat **nasal polyps**, nasal septal deviation, allergic nasal inflammation, chronic sinus infection, and swollen mucous membranes. One benefit of nasal irrigation in treating these conditions is that it usually lowers the amount of medication that the patient must take by mouth.

Irrigation is also used to treat long-term users of inhalants, such as illicit drugs (cocaine), or such occupational toxins as paint fumes, sawdust, pesticides, and coal dust.

Nasal irrigation may also be used in occupational medicine to monitor workers for exposure to airborne glass fibers, asbestos, and similar materials.



Because surgery in the nasal area has a high incidence rate for contamination with pathogenic bacteria, nasal irrigation is performed to remove loose tissue and prevent infection. The illustration (right) shows a cannula in place while the sinus passages are being flushed. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

KEY TERMS

Irrigation—In medicine, the practice of washing out or flushing a wound or body opening with a stream of water or another liquid.

Saline—A solution made from salt and water.

Precautions

Nasal irrigation should not be performed on people who have frequent nosebleeds; have recently had nasal surgery; or whose gag reflex is impaired, as fluid may enter the windpipe.

Description

Nasal irrigation can be performed by the patient at home or by a medical professional. A forced-flow instrument, such as a syringe, is filled with a warm saline solution. The solution can be commercially prepared (Ayr, NaSal) or can be prepared by the patient, using one-half teaspoon salt with each eight ounces of warm water. Occasionally, antibiotics or **steroids** are added to the solution to kill bacteria and aid healing of irritated membrane. The syringe is then directed into the nostril. The irrigation solution loosens encrusted material in the nasal passage, and drainage takes place through the nose. The patient leans over a catch basin during irrigation, into which the debris flows. Irrigation continues until all debris is cleared from the passage. Nasal irrigation can be performed up to twice daily, unless the irrigation irritates the mucous membrane.

Preparation

Before nasal irrigation, the patient is instructed not to open his or her mouth or swallow during the procedure. Opening the mouth or swallowing may cause infectious material to move from the nasal passage into the sinuses or the ear.

Risks

Complications of nasal irrigation include irritation of the nasal passages due to extreme temperature of the irrigation solution. Rarely, irrigation fluid may enter the windpipe in people with a poor gag reflex.

Nasal packing

Definition

Nasal packing is the application of gauze or cotton packs to the nasal chambers.

Purpose

The most common purpose of nasal packing is to control bleeding following surgery to the septum or nasal reconstruction and to treat chronic nosebleeds. Packing is also used to provide support to the septum after surgery.

WWW.BOOKBAZ.IR

Description

Packing is the placement of gauze or cotton into the nasal area. Packing comes in three forms: gauze, cotton balls, and preformed cotton wedges. Packing is usually coated with **antibiotics** and, sometimes, petrolatum. The end of the nose may be taped to keep the packings in place or to prevent the patient from pulling them out. In cases of surgery, packings are frequently removed within 24–48 hours following surgery. In the case of nosebleeds, packing is left in for extended periods of time to promote healing and to prevent the patient from removing scar tissue which might reopen the wound. If both sides of the nose are packed, the patient must breathe through his or her mouth while the packs are in place.

In patients who are chronic nose pickers, frequent bleeding is common and ulceration of nasal tissue is possible. To promote healing and to prevent nose picking, both sides of the nose are packed with cotton that contains antibiotics. The nose is taped shut with surgical tape to prevent the packing from being removed. The packing is left in the nose for seven to 10 days. If the wound is high up in the nasal cavity, gauze strips treated with petrolatum and antibiotics are used. The strips are placed into the nose one layer at a time, folding one layer on top of the other until the area is completely packed.

Local packing is a procedure used when only a small part of the nose must be packed. Typically, this occurs when one blood vessel is prone to bleeding, and there is no need to block breathing through the nose. Local packing is used when the pack can remain in place by itself. This situation can be found at the turbinates. Turbinates are folds of tissue on the insides of the nose. The folds are sufficiently firm to support packing. A small piece of gauze or cotton is wedged in between the turbinates where the blood vessel being treated is located. Local packing is left in place for up to 48 hours and then removed. The main advantage to this type of packing is that it enables the patient to breathe through his or her nose. Local packing is also more comfortable than complete packing, although the patient will still experience a sensation that something is in the nasal cavity. The patient must be instructed not to interfere with or probe the packing while it is in place.

A postnasal pack is used to treat bleeding in the postnasal area. This is a difficult area to pack. Packs used in this area are made from cotton balls or gauze that have been tied into a tubular shape with heavy gauge suture or umbilical tape. Long lengths of suture or tape are left free. The lengths of suture or tape are used to help position the pack during installation and to remove it. An alternative is to cut a vaginal tampon and reposition the strings. Balloons have been tried as a method to replace postnasal packing, but have not proved effective. After being tied, the pack is soaked with an antibiotic ointment. Generally, packs are formed larger than needed, so that they completely block the nasal passage. A catheter is passed through the nose and pulled out through the mouth. Strings from one end of the pack are tied to the catheter and the pack pulled into place by passing through the mouth and up the back of the nasal cavity. The pack is removed in a similar manner. Complications may occur if a pack compresses the eustachian tube, causing ear problems. The ear should be examined to ensure that infection is not developing.

KEY TERMS

Turbinate—Ridge-shaped cartilage or soft bony tissue inside the nose.

Ulcer—A sore on the skin or mucous tissue that produces pus and in which tissue is destroyed.

Packing of the anterior (front) part of the nose is also performed following surgery such as **septoplasty** and **rhinoplasty**. In these operations, the surgeon cuts through the skin flap covering cartilage and bone in the center, top, and bottom of the nose to correct the shape of the nose. At the conclusion of the surgery, the skin flap is sutured back into place. The purposes of packing are to absorb any drainage from the incision and mucus produced by nasal tissue, and to support the skin flap and cartilage. The packing used is either gauze or preformed adsorbent wedges of cotton. Both are usually treated with antibiotic to reduce the chance of infections at the incision site. Generally, there is little bleeding following septoplasty and rhinoplasty, and the incisions heal normally. These packs are left in place for 24 to 48 hours and then removed.

Aftercare

Ice chips or mouthwash can be used to moisten the mouth while packing is in place, as the mouth may be dry from breathing through it. Humidifiers may also help with breathing. After nasal packing, the nose should not be blown for two to three days.

Since one of the major reasons that packing is performed is to heal damage to nasal blood vessels from nose-picking, follow-up examination should be done to ensure that the patient is no longer practicing this habit. If the patient has restarted nose-picking, therapy to alter this behavior should be pursued. When the packing completely blocks the nasal cavity and prevents breathing through the nose, the patient should adjust to breathing through the mouth. In elderly patients, adjustment may be more difficult. This leads to a drop in the blood oxygen content and an increase in blood carbon dioxide levels (CO_2). This, in turn, can cause respiratory and cardiac complications, including a racing pulse.

Risks

Nasal packing could cause a lack of oxygen in those who have difficulty breathing through their mouths. Rarely, sinus infection or middle-ear infection may occur.

Nasal papillomas

Definition

Nasal papillomas are **warts** located inside the nose.

Description

Two types of tumors can grow inside the nose: polyps and papillomas. By far the most common are polyps, which have smooth surfaces. On the contrary, papillomas have irregular surfaces and are, in fact, warts. Papillomas may be caused by the same viruses that cause warts elsewhere on the body. They are inside the nose, more often on the side near the cheek, and, because of their internal structure, they are much more likely to bleed than polyps.

There is a special type of nasal papilloma called an inverting papilloma because of its unique appearance. About 10–15% of these are or can become cancers.

KEY TERMS

Polyp—A tumor commonly found in the nasal cavity or intestine.

Causes and symptoms

Like polyps, papillomas can plug up the nose and disable the sense of smell. Unlike polyps, papillomas often bleed.

Diagnosis

A **physical examination** with special instruments will detect these tumors.

Treatment

Because of the possibility of cancer, all nasal papillomas must be removed surgically and sent to the laboratory for analysis. If a cancer is present, further surgery may be necessary to guarantee that all of the cancer has been removed. The initial surgery can be done in an office setting by a specialist in head and neck surgery, also known as otorhinolaryngology and popularly abbreviated ENT (ear, nose, and throat). Cancer surgery is more extensive and often requires hospitalization.

Prognosis

For benign (non-cancerous) lesions, removal is curative, although they tend to recur, just like warts elsewhere. The cancerous papillomas may occasionally escape complete surgical removal and spread to adjacent or distant sites. The prognosis is then much more complex.

Nasal polyps

Definition

A polyp is the medical term for any overgrowth of tissue from the surface of a body organ. Polyps come in all shapes—round, droplet, and irregular being the

WWW.BOOKBAZ.IR

A nasal polyp inside patient's right nostril. *(Custom Medical Stock Photo, Inc.)*

most common. Nasal polyps are teardrop-shaped while growing and resemble peeled grapes when they have reached their full size. The condition of nasal polyps is sometimes called nasal polyposis.

Description

Nasal polyps tend to occur in people with respiratory **allergies**. Hay **fever** (**allergic rhinitis**) is an irritation of the membranes of the nose by airborne particles or chemicals. These membranes secrete mucus. When irritated, they can also grow polyps. The nose is not only a passageway for air to reach the lungs; it also provides the connection between the sinuses and the outside world. Sinuses are lined with mucous membranes, just like the nose. Polyps can easily obstruct the drainage of mucus from the sinuses. When any fluid in the body is trapped so it cannot flow freely, it becomes infected. The result, **sinusitis**, is a common complication of allergic **rhinitis**.

Nasal polyps may also develop in children with **cystic fibrosis**.

Causes and symptoms

Some people who are allergic to **aspirin** develop both **asthma** and nasal polyps.

Nasal polyps often plug the nose, usually one side at a time. People with allergic rhinitis are so used to having a stopped-up nose they may not notice the difference when a polyp develops. Other polyps may be closer to a sinus opening, so airflow is not obstructed, but mucus becomes trapped in the sinus. In this case, there is a feeling of fullness in the head, no sense of smell, and perhaps a **headache**. The trapped mucus will eventually get infected, adding **pain**, fever, and perhaps bloody discharge from the nose.

KEY TERMS

Allergen—Any substance that irritates only those who are sensitive (allergic) to it.

Asthma—Wheezing (labored breathing) due to allergies or irritation of the lungs.

Decongestant—Medicines that shrink blood vessels and consequently mucus membranes. Pseudoephedrine, phenylephrine, and phenylpropanolamine are the most common.

Polyposis—The medical term for the development of multiple polyps on a body part.

Sinus—Air-filled cavities surrounding the eyes and nose are lined with mucus-producing membranes. They cleanse the nose, add resonance to the voice, and partially determine the structure of the face.

Diagnosis

A **physical examination** will identify most polyps. Small polyps located higher up or further back may be hidden from view, but they will be detected with more sophisticated medical instruments. The otorhinolaryngologist is equipped to diagnose nasal polyps. In order to perform the examination, the doctor must apply medicine to reduce congestion in the swollen membranes. Cotton balls soaked with one of these agents and left in the nostrils for a few minutes provide adequate shrinkage.

Treatment

Most polyps can be removed by the head and neck surgeon as an office procedure called a nasal polypectomy. Bleeding, the only complication, is usually easy to control. Nose and sinus infections can be treated with **antibiotics** and **decongestants**, but if airflow is restricted, the infection will recur.

Prognosis

Polyps may reappear as long as the allergic irritation continues. In addition, one study of patients who had undergone nasal polypectomy reported that 60% had a recurrence of nasal polyposis, and 47% were advised to have revision surgery. The risk of recurrence is higher among patients with asthma.

Prevention

If aspirin is the cause of the polyps, all aspirin containing medications must be avoided.

Since most nasal polyps are the result of allergic rhinitis, they can be prevented by treating this condition. New treatments have greatly improved control of hay fever. There are now several spray medicines that are quite effective. Spray cortisone-like drugs, usually beclomethasone (Beconase, Vancenase) or flunisolide (Nasalide), are the most popular. Over-the-counter nasal decongestants have an irritating effect similar to the allergy they are supposed to be treating. Continued use can bring more trouble than relief and result in an **addiction** to nose sprays. The resulting disease, rhinitis medicamentosa, is more difficult to treat than allergic rhinitis.

Allergists and ENT surgeons both treat allergic rhinitis with a procedure called desensitization. After identifying suspect allergens using one of several methods, they will give the patient increasing doses of those allergens in order to produce blocking antibodies that will impede the allergic reaction. This approach is effective in a number of patients, but the treatment may take a period of months to years.

Nasal trauma

Definition

Nasal **trauma** is defined as any injury to the nose or related structure that may result in bleeding, a physical deformity, a decreased ability to breathe normally because of obstruction, or an impaired sense of smell. The injury may be either internal or external.

Fractured nose of an elderly patient. *(Dr. P. Marazzi/Photo Researchers, Inc.)*

Description

The human nose is composed of bone, soft tissue, and cartilage. It serves as a passageway for air to flow from the outside environment into the lower respiratory tract and lungs. At the same time, the nasal passages warm and humidify the air that enters the body.

Internal injuries to the nose typically occur when a foreign object (including the fingers) is placed in the nose or when a person takes in drugs of abuse (inhalants or cocaine) through the nose. External injuries to the nose are usually blunt force injuries related to sports participation, criminal violence, parental abuse, or automobile or bicycle accidents. This type of injury may result in a nasal fracture. The nasal bones are the most frequently fractured facial bones due to their position on the face, and are the third most common type of bone fracture in general after **fractures** of the wrist and collarbone. A force of only 30g is required to break the nasal bones, compared to 70g for the bones in the jaw and 200g for the bony ridge above the eyes. The pattern of the fracture depends on the direction of the blow to the nose, whether coming from the front, the side, or above the nose. Although not life-threatening by itself, a fractured nose may lead to difficulties in breathing as well as facial disfigurement.

Fractures resulting from trauma to the nose may involve the bones of the septum (the partition of bone and cartilage dividing the two nostrils) as well as the bones surrounding the eyes. These bones include the nasal, maxilla, lacrimal, and frontal bones. Direct

WWW.BOOKBAZ.IR

trauma to the bridge of the nose may also result in damage to a part of the base of the skull known as the cribriform plate. This injury in turn may allow cerebrospinal fluid to leak out of the skull and leave the body through the nose. Fractures may also damage the membranes that line the nasal passages, leading to possible formation of scar tissue, obstruction of the airway, and damage to the child's sense of smell.

In addition to fractures, external injuries of the nose include soft-tissue injuries resulting from bites (human and animal), insect stings, cuts, or scrapes. Penetrating injuries to the nasal area caused by air gun or BB pellets are also reported with increasing frequency in older children and adolescents. When fired at close range, these pellets can penetrate the skin and cheekbone and lodge in the nasal septum or the sinuses near the nose.

Lastly, nose piercing as a fashion trend is a type of intentional injury to the nose that has several possible complications, including infections of the cartilage and soft tissues in the nose; blockage of the airway due to a loosened stud or other nose ornament; and gastrointestinal emergencies caused by accidental swallowing of nose jewelry.

Causes and symptoms

Causes

External trauma to the nose may be accidental (transportation accidents, animal bites, air gun injuries, and **sports injuries**) or intentional (fights, criminal assault, domestic violence, nose piercing). Nasal injuries from athletic activities may result from contact with equipment (being hit in the face by a baseball, or other small ball hit at high speed, or by the bat or stick itself) or the bodies of other players (in sports such as football, boxing, martial arts, rugby). Nasal injuries from piercing include bacterial infections of the skin and nasal cartilage, allergic reactions to the jewelry, tissue damage, and periodic bleeding.

In a few cases, external trauma to the nose may also be iatrogenic, or caused by medical care. Most of these injuries result from medical examination of the nose—particularly in emergency circumstances—or as complications of **plastic surgery**. In a few cases damage to the nose is caused by **radiation therapy** for cancer.

Internal injuries to the nose may be either mechanical (caused by **foreign objects** in the nose or by picking or scratching the tissues lining the nose) or chemical (caused by environmental irritants or substance abuse).

Chemical injuries to the nose are caused by accidental or purposeful breathing or sniffing of irritating substances. These may include tobacco smoke; household cleaners (ammonia and chlorine bleach) and furniture polish; ozone and other air pollutants; cocaine; and glue, paint thinners, solvents, and similar household products that produce toxic vapors. An increasingly common form of chemical injury to the nasal membranes in toddlers is alkali **burns** caused by leakage from small batteries placed in the nose. While chemical damage to the nose is usually accidental in younger children, it is more often the result of substance abuse in adolescents. Taking cocaine through the nose ("snorting") or inhalant abuse ("sniffing" or "huffing") are the most common causes of chemical damage to the nose in older children or teenagers.

Symptoms

The symptoms of physical trauma to the nose may include:

- Flattening or other deformation of the shape of the nose
- Infections of the cartilage or soft tissue
- Epistaxis or bleeding from the nose
- Crepitus. Crepitus is the crackling or crunching sound heard when the ends of a fractured bone are rubbed together
- Pain and tissue swelling
- Airway blockage from bleeding, fluid discharge, or tissue swelling
- Rhinitis. Rhinitis is an inflammation of the mucous membranes lining the nose. In the case of a fracture, rhinitis may lead to increased tear production in the eyes and a runny nose
- Septal hematoma. A septal hematoma is a mass of blood from torn tissue that may collect within the cartilage that divides the two nostrils. It may become infected and form an abscess that eventually destroys the cartilage
- Bruising or discoloration (ecchymosis) of the tissues around the eye
- Leakage of cerebrospinal fluid through the nostrils

Chemical trauma to the nose may result in:

- Runny nose and watering of the eyes
- Pain
- Loss of the sense of smell
- Nasal congestion and sneezing
- Reddening and swelling of the mucous membranes lining the nose

- Eventual destruction of the cartilage in the nasal septum and the tissues lining the nose

Some common irritants that may be encountered in the home and workplace include:

- cleaning solutions and powders
- ammonia
- environmental tobacco smoke
- bleach
- metalworking fluids
- ozone
- sulfur dioxide
- paint thinners
- arsenic
- chromic acid
- copper dust and mists

Aftereffects following exposure to these chemicals are based not only on the concentration of the irritant but also on factors specific to the individual. Reactions vary among persons, even with similar exposures.

Diagnosis

Diagnosis of a fracture is normally based on a history of nasal trauma and clinical presentation. Epistaxis may or may not be present. An intranasal examination is performed in order to look for a septal hematoma that may result in serious consequences such as death of the septal cartilaginous tissue. The nose is also checked for tenderness, mobility, stability, and crepitance.

X rays are normally not indicated, however, in more severe fractures involving multiple bones, a computed tomography (CT) scan may be required. The physician should look for associated injuries such as periorbital (surrounding the eye) ecchymosis, watery eyes, or diplopia (double vision) that may indicate orbital injuries. In addition, dental fractures and a cerebrospinal fluid (CSF) leak should be looked for. CSF leaks indicate a more severe injury possibly involving an ethmoid bone fracture.

The physician may also ask for photographs taken prior to the injury in order to determine the extent of deformity. Photographs may also be taken to document the injury in regards to possible legal actions.

In order to diagnose trauma sustained by a chemical injury, a history of exposure to potentially toxic chemicals should be ascertained. In addition, the patient should also bring information related to the types of chemicals that he or she has been exposed to. If injury occurs in the workplace, Material Safety Data Sheets should be available in the employer's poison control center that list the chemical components of commercial materials. Measurements of air from the patient's work area may also be obtained. Symptomatic improvement on off-days followed by a subsequent return of symptoms when returning to work confirms that the illness is work related. The physician should perform an intranasal examination to determine the extent of the chemical injury. A **chest x ray** as well as a pulmonary function test may be ordered to determine if there is any subsequent lower respiratory tract involvement.

Treatment

Timing

Nasal injuries should be treated as promptly as possible to prevent complications. Batteries placed in the nose should be removed within four hours to prevent burns and other damage to the tissues from leaking chemicals. If a septal hematoma has developed, the doctor must remove it as quickly as possible to prevent infection or eventual death of the tissues in the nasal septum. Lastly, if the child has been bitten by an animal, the injury must be cleansed as soon as possible to lower the risk of **rabies**.

Treatment of nasal fractures is best performed during the first three hours after the injury. If this is impossible, management of a nasal fracture should be done within three to seven days. Timing is of utmost importance when treating nasal fractures because delays longer than seven to 10 days may allow the broken bones to set without proper alignment, or lead to such complications as scar tissue formation and airway obstruction. Poorly set nasal fractures usually require surgical correction.

Specific procedures

Foreign objects in the nose can be removed by nasal suction in most cases. Most nosebleeds are treated by 5–30 minutes of direct pressure on the nostrils, with the patient's head placed in an upright position. The doctor may also pack the nose with gauze coated with petroleum jelly. If the bleeding does not stop, or if it appears to originate in the upper nose, the doctor will consult a head and neck surgeon or an otolaryngologist for specialized evaluation of the bleeding.

Air gun or BB pellets that have penetrated the nose or nearby sinuses are generally removed with the help of an endoscope, which is a slender tubular instrument that allows the doctor to examine the inside of a body cavity.

WWW.BOOKBAZ.IR

Treatment of nasal fractures depends on the extent of the injury; the most difficult fractures to treat are those that involve the nasal septum. The doctor will usually reduce the fracture, which means that he or she will restore the damaged bones to their proper position and alignment. Although local **anesthesia** is usually sufficient for treating nasal fractures in adults and older teenagers, general anesthesia is usually given when treating these injuries in younger children.

Reductions of nasal fractures may be either open or closed. A closed reduction involves manipulation of the bones without cutting into the overlying skin. This type of reduction will be performed for fractures of the nasal bones that are limited in size and complexity. Open reductions are performed for more complex nasal fractures. In an open reduction, the nasal bones are moved back to their original location after the surgeon has made an incision in the overlying skin. This procedure is done for fractures involving dislocation of the septum as well as the nasal bones. In addition, an open reduction is necessary if the child has a septal hematoma or an open fracture in which the skin has been perforated. If a septal hematoma is present, the doctor will drain it and pack the nose to prevent subsequent accumulation of blood. The nasal bones are held in the proper position with external splints as well as the internal packing, and the splints are kept in place for seven to 10 days. The patient will be given **antibiotics** to lower the risk of infection and may be referred to an otolaryngologist or plastic surgeon for further evaluation. Ice packs or cold compresses can be applied at home to lower swelling and ease discomfort.

In the case of animal bites, the patient may be given passive or active immunization against rabies if there is a chance that the dog or other animal is rabid. This precaution is particularly important for animal bites on the nose or other parts of the face, as the incubation period of the rabies virus is much shorter for bites on the head and neck than for bites elsewhere on the body.

Complications can arise following treatment and therefore follow-up is necessary. Problems that may occur resemble symptoms of nasal fractures. Others include infection, CSF leakage, scar tissue build-up, and a saddle nose deformity where the bridge of the nose is markedly depressed.

Treatment for trauma caused by irritant inhalation involves removing the patient from the contaminated area or decreasing exposure time. Other measures include using a saline nasal spray or topical **steroids**. For acute injuries oxygen or supportive treatment for any subsequent lower respiratory tract involvement may be administered.

KEY TERMS

Crepitus—A crackling or crunching sound heard when the ends of a fractured piece of bone rub against each other.

Diplopia—The medical term for seeing double.

Ecchymosis (plural, ecchymoses)—The medical term for a bruise. Ecchymoses may develop around the eyes following a nasal fracture.

Epistaxis—The medical term for a nosebleed.

Hematoma—A localized collection of blood that accumulates in an organ, tissue, or body space as the result of leakage from a broken blood vessel. Hematomas sometimes develop within the nasal cartilage when the nose is fractured.

Iatrogenic—Referring to injuries caused by a doctor. Nasal trauma may occasionally result from a doctor's examination of the nose or complications from plastic surgery.

Otolaryngologist—A doctor who specializes in diagnosing and treating disorders of the ears, nose, and throat.

Reduce—To restore a part of the body to its normal position or place, as in treating a fracture or dislocation. The repositioning of the bone or body part is called a reduction.

Rhinitis—An inflammation of the mucous membranes that line the nasal passages.

Rhinoplasty—Plastic surgery of the nose to repair or change the shape of the nose.

Septal hematoma—A mass of extravasated blood that is confined within the nasal septum.

Septum—The partition of bone and cartilage in the nose that separates the two nostrils.

If the injury is occupation-related, changes should be made in order to eliminate future incidents. These changes may include having the patient wear a respiratory protection device while working. In addition, the employer should be made aware of the situation and employ measures to prevent future incidents.

Prognosis

Most types of nasal trauma have a good prognosis. Nosebleeds or tissue damage caused by scratching or picking at the nose usually clear completely once these habits are stopped. Infections or allergic reactions caused by foreign objects in the nose or piercing

usually clear up promptly after the object or piece of jewelry is removed. Nasal fractures that do not involve the nasal septum or other facial bones and receive prompt treatment generally heal without deformities of the nose, cartilage destruction, or other complications. More extensive facial fractures, however, may require a second operation to correct the positioning of the bones and restore the appearance of the nose.

The prognosis for soft-tissue injuries to the nose depends on the cause and extent of the injuries. Such tearing or crushing injuries as those caused by bites take longer to heal than simple cuts, and may require plastic surgery at a later date to restore the appearance of the nose.

Damage to the tissues lining the nose caused by exposure to tobacco smoke or other irritants in the environment is usually reversible once the patient is removed from contact with the irritating substance. Erosion or destruction of the nasal cartilage as a result of inhalant or cocaine abuse, however, usually requires surgical treatment.

Prevention

Although most cases of nasal trauma happen inadvertently, some measures can be employed in order to prevent injury. Patients should be aware of the symptoms of nasal fracture and should seek medical attention as soon as possible to prevent more invasive reductions. Protective equipment should also be worn when playing sports. Employees should also be aware of irritating chemicals in their workplace and appropriate measures should be taken to avoid exposure.

Nasogastric (NG) tube

Definition

A nasogastric (NG) tube is a flexible tube that is inserted through the nose into the stomach. It can be used for either diagnostic or therapeutic purposes. When the tube is threaded through the mouth into the stomach, it is referred to as an orogastric (OG) tube.

Purpose

A nasogastric tube can be used:

- to decompress the stomach or small intestine of gas, digestive juices, or other contents when intestinal blockage is suspected
- prior to gastrointestinal operations
- to obtain a sample of the gastric contents for analysis

WWW.BOOKBAZ.IR

- to remove toxic substances
- to flush the stomach during gastrointestinal bleeding or poisonings
- to instill radiographic dyes prior to imaging tests
- to feed
- to administer medications

Precautions

Nasogastric tubes cannot be placed in patients who have blockages in their esophagus, enlarged esophageal veins or arteries that might bleed, or severe damage to the jaws and face. The tube should not be inserted in a patient who is having convulsions, or who is losing or has lost consciousness unless a different tube already has been inserted into his or her airway (endotracheal intubation) to prevent stomach contents from entering the lungs.

Description

Ideally, the patient sits upright while the lubricated tube is slipped through the nose and down the throat. The patient may be asked to sip water at a certain point in the procedure to facilitate the passage of the tube. If the tube is to be advanced beyond the stomach and into the small intestine, the doctor may use an endoscope to help see where the tube is going. Once the tube is in place, material can be removed from the stomach or intestines by attaching the tube to a low amount of suction.

Nasogastric tubes come in a variety of materials, designs, and calibers. The size chosen depends on the age/size of the patient, and the tube's intended use. Larger diameters are required to suction out thicker stomach contents (such as **blood clots** or undigested food), as with poisonings or overdoses. There are several different types of nasogastric tube's each with a different purpose. Tubes that are threaded through the lower opening of the stomach (pylorus) and into the small intestine are stiffer and have a balloon tip. Other specialized tubes are used for long-term and short-term feeding.

Preparation

Little preparation is necessary for this procedure other than educating the patient as to what will happen. The patient should remove dental appliances before the nasogastric tube is inserted. A numbing agent such as lidocaine may be applied to the nose or throat to reduce discomfort. The patient is asked to sit up, with the chin tipped towards the chest. As the tube is inserted, the patient will be asked to take a sip of water to help the tube pass more easily. When the tube is in place, it will be taped securely to keep it from slipping out.

KEY TERMS

Endoscope—A piece of equipment with a camera and a light source in a thin fiberoptic tube that can be threaded through the nose into the gastrointestinal system so that the doctor see inside the organs..

Pylorus—The ring of muscle that controls the passage of material from the stomach into the small intestine.

Aftercare

After the tube is removed, no special care is needed. The patient's throat may feel irritated from the presence of the tube.

Results

After the nurse or other medical worker inserts an NG tube, it is necessary to check immediately that it is in the stomach as intended. The patient should not be newly agitated or coughing. A simple test is to use a syringe to blow air into the open end of the tube while listening with a stethoscope for airflow in the stomach. Also, pulling back on the syringe ideally demonstrates expected stomach contents. In some cases the doctor will order an x ray to check the position of the tube. Nasogastric suctioning is usually well tolerated by patients, at least after initial discomfort subsides,

Risks

The most serious risk is that the patient will inhale some of the stomach contents into the lungs (aspiration). This may lead to bronchial infections and aspiration **pneumonia**. There is also the chance that the tube will be misplaced in the windpipe (trachea), causing violent coughing. Irritation to the throat and esophagus can cause bleeding. If the patient had an unrecognized fracture at the base of the skull, an NG tube could potentially pass into the brain cavity instead of going down the throat

Nasopharyngeal culture

Definition

A nasopharyngeal culture is used to identify pathogenic (disease-causing) organisms present in the nasal cavity that may cause upper respiratory tract symptoms.

Purpose

Some organisms that cause upper respiratory infections are carried primarily in the nasopharynx, or back of the nose. The person carrying these pathogenic bacteria may have no symptoms, but can still infect others with the pathogen and resulting illness. The most serious of these organisms is *Neisseriea meningitidis*, which causes **meningitis** or bloodstream infection in infants. By culturing a sample from the nasopharynx, the physician can identify this organism, and others, in the asymptomatic carrier. The procedure can also be used as a substitute for a **throat culture** in infants, the elderly patient, the debilitated patient, or in cases where a throat culture is difficult to obtain.

Precautions

The technician taking the specimen should wear gloves to prevent spreading infectious organisms. The patient should not be taking **antibiotics**, as these drugs may influence the test results.

Description

The patient should **cough** before collection of the specimen. Then, as the patient tilts his or her head backwards, the caregiver will inspect the back of the throat using a penlight and tongue depressor. A swab on a flexible wire is inserted into the nostril, back to the nasal cavity and upper part of the throat. The swab is rotated quickly and then removed. Next, the swab is placed into a sterile tube with culture fluid in it for transport to the **microbiology** laboratory. To prevent contamination, the swab should not touch the patient's tongue or side of the nostrils.

When the sample reaches the laboratory, the swab will be spread onto an agar plate and the agar plate incubated for 24–48 hours, to allow organisms present to grow. These organisms will be identified and any pathogenic organisms may also be tested for susceptibility to specific antibiotics. This allows the treating physician to determine which antibiotics will be effective.

Alternative procedures

In most cases of upper respiratory tract infections, a throat culture is more appropriate than a nasopharyngeal culture. However, the nasopharyngeal culture should be used in cases where throat cultures are difficult to obtain or to detect the carrier states of *Harmophilus influenzae* and meningococcal disease.

Some researchers regard the immunoblot method as preferable to a standard culture to detect certain species of pneumococci and other organisms that cause **pneumonia**. The immunoblot method uses a membrane that changes color in response to a specific antigen-antibody reaction.

Presently, polymerase chain reaction (PCR) analysis is considered more sensitive than standard culture in detecting *Bordetella pertussis*, the bacterium that causes whooping cough. PCR has the additional advantage of providing test results more rapidly than culture.

Preparation

The procedure of inserting the swab should be described to the patient, as there is a slight discomfort associated with taking the sample. Other than that, no special preparation is necessary.

Aftercare

None.

Results

Bacteria that normally grow in the nose cavity will be identified by a nasopharyngeal culture. These include nonhemolytic streptococci, alpha-hemolytic streptococci, some *Neisseria* species, and some types of staphylococci.

Abnormal results

Pathogenic organisms that might be identified by this culture include

- Group A beta-hemolytic streptococci
- *Bordetella pertussis*, the causative agent of whooping cough

WWW.BOOKBAZ.IR

KEY TERMS

Antibiotic—A drug given to stop the growth of bacteria. Antibiotics are ineffective against viruses.

Nasopharynx—The back wall of the nasal cavity where it meets the throat.

- *Corynebacterium diptheriae*, the causative agent of diptheria
- *Staphylococcus aureus*, the causative agent of many staphylococcal infections

Additional bacteria are abnormal if they are found in large amounts. These include

- *Haemophilus influenzae*, a causative agent for certain types of meningitis and chronic pulmonary disease
- *Streptococcus pneumoniae*, a causative agent of pneumonia
- *Candida albicans*, the causative agent of thrush

Risks

There is little to no risk involved in a nasopharyngeal culture.

Native American health *see* **Minority health**

Naturopathic medicine

Definition

Naturopathic medicine is a branch of medicine in which a variety of natural medicines and treatments are used to heal illness. It uses a system of medical diagnosis and therapeutics based on the patterns of chaos and organization in nature. It is founded on the premise that people are naturally healthy, and that healing can occur through removing obstacles to a cure and by stimulating the body's natural healing abilities. The foundations of health in natural medicine are diet, **nutrition**, homeopathy, physical manipulation, **stress** management, and **exercise**.

Naturopaths are general practitioners who treat a wide variety of illnesses. They believe in treating the "whole person"—the spirit as well as the physical body—and emphasize preventive care. They often recommend changes in diet and lifestyle to enhance the health of their patients.

Purpose

Naturopathic medicine is useful for treating chronic as well as acute diseases. It is sometimes used in conjunction with allopathic care to enhance wellness and relieve chronic symptoms, such as **fatigue** and **pain**. A naturopath treats a wide range of health problems, ranging from back pain to depression.

A naturopathic physician will spend extra time interviewing and examining the patient to find the underlying cause for a medical problem. Emotional and spiritual symptoms and patterns are included in the assessment. The naturopath often spends more time educating patients in preventive health, lifestyle, and nutrition than most MDs.

Description

Origins

People have always seen a connection to diet and disease, and many therapies are built around special **diets**. Naturopathy began in the 18th and 19th centuries, as the industrial revolution brought about unhealthy lifestyles, and the European custom of "taking the cure" at natural spas became popular. Benedict Lust, who believed deeply in natural medicine, organized naturopathy as a formal system of healthcare in the 1890s. By the early 1900s, it was flourishing.

The first naturopaths in the United States emphasized the healing properties of a nutritious diet, as did a number of their contemporaries. In the

early twentieth century, for instance, John Kellogg, a physician and vegetarian, opened a sanitarium that used healing methods such as **hydrotherapy**, often prescribed by today's naturopaths. His brother Will produced health foods, such as corn flakes and shredded wheat. The Kellogg brothers helped make naturopathic ideas popular and emphasized the value of whole grains over highly refined ones. They and one of their employees, C.W. Post, eventually went on to start the cereal companies that bear their names.

In the early 1900s, most states licensed naturopaths as physicians. There were 20 medical schools of naturopathic medicine. From early on, naturopathic physicians were considered "eclectic," since they drew on a variety of natural therapies and traditions for treating their patients.

In the 1930s, naturopathy dramatically declined for several reasons. Allopathic medicine finally stopped using therapies such as bloodletting and **heavy metal poisoning** as curatives. New therapies were more effective and less toxic. Allopathic medical schools became increasingly well-funded by foundations with links to the emerging drug industry. Also, allopathic physicians became much more organized and wielded political clout. Naturopathy has experienced a resurgence over the last 20 years, however. The lay public is aware of the connection between a healthy diet and lifestyle and avoiding chronic disease. In addition, conventional medicine is often unable to treat these chronic diseases. Patients are now healthcare consumers, and will seek their own resolution to health problems that cannot be resolved by conventional physicians. As a result, even medical groups which once considered naturopathy ineffective are now beginning to accept it.

Naturopathic medicine modalities include a variety of healing treatments, such as diet and clinical nutrition, homeopathy, botanical medicine, soft tissue and spinal manipulation, **ultrasound**, and therapeutic exercise. A naturopath provides complete diagnostic and treatment services in sciences such as obstetrics, pediatrics and obstetrics. Some are also licensed midwives.

Naturopaths consider health to be not just the absence of disease, but complete physical, mental and social well-being. Naturopathic physicians often say that diseases must be healed not just by suppressing symptoms, but by rooting out the true cause. Symptoms are actually viewed as the body's natural efforts to heal itself and restore balance.

A typical office visit to a naturopath takes an hour. During the first visit, the doctor will ask detailed questions about the patient's symptoms, lifestyle, history of illness, and state of his or her emotions. The naturopath will take a complete medical history, and may order lab tests such as urine and blood tests. A naturopath may talk with the patient about the possible causes for an illness: poor diet, life stresses, occupational dangers, and mental, emotional, and spiritual problems. Naturopaths believe that even widely varying symptoms can sometimes be traced to one underlying cause. Often environmental or metabolic toxins or serious stress bring on an illness.

In some states, naturopaths prescribe pharmaceuticals. In these cases, naturopaths might prescribe natural medicines, such as natural hormones, glandular **thyroid hormones**, herbal extracts, **vitamins**, etc.

As with most doctors, treatment by a naturopath can range from one office visit to many. Some acute illnesses can be alleviated with one or two visits. Other chronic diseases need regular weekly or monthly attention. Clinical care provided by naturopathic physicians are covered by insurance in a number of states in the United States.

Preparations

There are about 1,500 naturopathic physicians in the United States practicing; nearly 80% of these practitioners entered the profession following the revival of interest in naturopathy in the late 1970s. Consumers can find naturopaths by contacting the American Association of Naturopathic Physicians (AANP) or logging on to their web site. Naturopaths recommended by the AANP have met requirements for state licensure and have taken a national exam that qualifies them to practice. Qualified naturopaths can also be found through the local branch of the national or state association of naturopathic physicians. It is sometimes useful to request names from another healthcare provider who knows naturopathic practitioners in the community.

Some states license naturopathic physicians. As of late 2014, those states included Hawaii, Alaska, Colorado, Washington, Oregon, Utah, Montana, Arizona, Connecticut, New Hampshire, Vermont, Maine, California, Idaho, Maryland, Minnesota, and Kansas, in addition to the territories of Puerto Rico and the Virgin Islands. Training via a correspondence school does not qualify a naturopath for licensure or to take the national qualifying examination.

Precautions

A good naturopath is always willing to work with the patient's other physicians or healthcare providers.

WWW.BOOKBAZ.IR

To avoid **drug interactions** and to coordinate care, it is important for a patient to inform his or her allopathic doctor about supplements prescribed by a naturopath.

Many naturopaths give childhood vaccinations, but some do not. If a parent is concerned about this, it is best to go to an allopathic doctor for vaccinations.

Naturopaths are not licensed to perform major surgery, or prescribe **narcotics** and **antidepressant drugs**. They must involve an oncologist when treating a cancer patient.

Side effects

Although naturopathic remedies are from natural sources and typically pose much less risk than traditional drugs do, some do have side effects. One problem they can pose is the interaction with prescription medicines. It is important for a patient to inform his or her allopathic physician about any natural remedies or herbs prescribed by a naturopath.

It is also important to note that the U.S. Food and Drug Administration considers medicinal herbs as dietary supplements, not drugs, and so are not subject to the same regulations as drugs are. Because they come from natural sources, the active ingredients may not always be in the same concentration from bottle to bottle, since plants naturally vary. To guard against using too little or too much of a natural remedy, use herbs and supplements recommended by a naturopath or those produced by well-respected companies.

Research and general acceptance

Medical research in naturopathy has increased dramatically in the United States within the last 10 years. Naturopathic research often employs case histories, summaries of practitioners' clinical observations, and medical records. Some U.S. studies have also met today's scientific gold standard; they were double-blind and placebo-controlled. Much naturopathic research has also been done in Germany, France, England, India, and China.

Some mainstream medical practitioners remain distrustful of naturopathy, however. Such problems as health-food store employees without naturopathic credentials giving health-related advice to customers, or occasional rare cases of infections caused by naturopathic injections, continue to damage the reputation of this form of alternative medicine.

Research in naturopathy tends to focus on single treatments used by naturopaths, rather than naturopathy as a whole. In 1998, an extensive review of such single treatment studies found that naturopathic healing methods were effective for 15 different medical conditions, including **osteoarthritis**, **asthma**, and middle ear infections. A study of 8,341 men with damaged heart muscles in 1996 revealed that supplementation with niacin, a B vitamin, was associated with an 11% reduced risk of mortality over 15 years. In 1996, a study showed St. John's wort was as effective as prescription antidepressants in relieving depression, and had fewer side effects.

Studies have also demonstrated benefits in the arena of women's health issues. In one classic 1993 study, women with cervical dysplasia or abnormal Pap smears were treated by naturopaths with topical applications of herbs and dietary supplements. These medications included Bromelian, an enzyme from the pineapple; bloodroot; marigold; and zinc chloride; and suppositories made from herbal and nutritional ingredients, such as **echinacea**, **vitamin A**, and **vitamin E**. Thirty eight of the 43 women in the study had normal Pap smears and normal tissue biopsies after treatment. The study concluded that these protocols might benefit the health of patients undergoing more traditional treatments for cervical dysplasia, such as **cryotherapy**.

Other more recent research has documented the benefits of such nutritional foods as soy in relieving hot flashes and vaginal dryness. **Nutritional supplements**

KEY TERMS

Clinical nutrition—The use of diet and nutritional supplements as a way to enhance health prevent disease.

Cryotherapy—The exposure of body tissue to extremely cold temperatures, often by applying a probe containing liquid nitrogen.

Herb—In naturopathy, a plant or plant derivative or extract prescribed for health or healing.

Homeopathy—The use of diluted remedies that have energetic rather than chemical properties. They are prescribed according to the axiom that "like cures like."

Hydrotherapy—The use of water as baths, poultices, and steams to heal.

Physical manipulation—The use of deep massage, spinal alignment, and joint manipulation to stimulate tissues.

Ultrasound—A therapy employing high frequency sound waves.

prescribed by naturopaths to enhance women's health during **menopause** have also proven effective; in general, naturopathy appears to be as useful as conventional medicine for treating menopausal symptoms. Research shows vitamin E supplements are helpful for 50% of postmenopausal women with thinning vaginal tissue. Studies also reveal that bioflavonoids with vitamin C and gamma-oryzanol, a substance taken from rice bran oil, can relieve hot flashes.

Another area of women's health concerns that naturopathy has taken seriously is a growing preference for skin care and beauty products derived from natural sources rather than from chemical laboratories. Such products are often more beneficial to the skin and less likely to cause **rashes** or other allergic reactions.

Nausea and vomiting

Definition

Nausea is the sensation of being about to vomit. **Vomiting**, or emesis, is the expelling of undigested food through the mouth.

Description

Nausea is a reaction to a number of causes that include overeating, infection, or irritation of the throat or stomach lining. Persistent or recurrent nausea and vomiting should be checked by a doctor.

A doctor should be called if nausea and vomiting occur:

- after eating rich or spoiled food or taking a new medication
- repeatedly or for 48 hours or longer
- following intense dizziness

It is important to see a doctor if nausea and vomiting are accompanied by:

- yellowing of the skin and whites of the eyes
- pain in the chest or lower abdomen
- trouble with swallowing or urination
- dehydration or extreme thirst
- drowsiness or confusion
- constant, severe abdominal pain
- a fruity breath odor

A doctor should be notified if vomiting is heavy and/or bloody, if the vomitus looks like feces, or if the patient has been unable to keep food down for 24 hours.

An ambulance or emergency response number should be called immediately if:

- Diabetic shock is suspected.
- Nausea and vomiting continue after other symptoms of viral infection have subsided.
- The patient has a severe headache.
- The patient is sweating and having chest pain and trouble breathing.
- The patient is known or suspected to have swallowed a drug overdose or poisonous substance.

WWW.BOOKBAZ.IR

These illustrations depict the mechanism and causes of vomiting in the human body. An impulse from the brain stimulates the vomiting center (top center) in the brain stem. Nerve impulses sent to the stomach, diaphragm, and abdominal wall (bottom center) result in stomach's contents being expelled. Other causes of vomiting include raised pressure in the skull due to injury or tumor (upper right), and hormonal changes during pregnancy. *(Custom Medical Stock Photo, Inc.)*

- The patient has a high body temperature, muscle cramps, and other signs of heat exhaustion or heat stroke.
- Nausea, vomiting, and breathing problems occur after exposure to a known allergen.

Causes and symptoms

Persistent, unexplained, or recurring nausea and vomiting can be symptoms of a variety of serious illnesses. It can be caused by simply overeating or drinking too much alcohol. It can be due to **stress**, certain medications, or illness. For example, people who are given morphine or other opioid medications for **pain** relief after surgery sometimes feel nauseated by the drug. Such poisonous substances as arsenic and other heavy metals cause nausea and vomiting. Morning sickness is a consequence of pregnancy-related hormone changes. **Motion sickness** can be induced by traveling in a vehicle, plane, or on a boat. Many patients experience nausea after eating spoiled food or foods to which they are allergic. Patients who suffer **migraine headache** often experience nausea. Cancer patients on **chemotherapy** are nauseated. **Gallstones**, **gastroenteritis** and stomach ulcer may cause nausea and vomiting. These symptoms should be evaluated by a physician.

Nausea and vomiting may also be psychological in origin. Some people vomit under such conditions of emotional stress as family arguments, academic tests, airplane travel, losing a job, and similar high-stress situations. In addition, some **eating disorders** are characterized by self-induced vomiting.

Diagnosis

Diagnosis is based on the severity, frequency, and duration of symptoms, and other factors that could indicate the presence of a serious illness.

Diagnosis is based on the taking of a careful patient history. In some cases, the doctor may order laboratory tests or imaging studies to determine the presence of drugs or poisonous substances in the patient's blood or urine, or evidence of head injuries or abnormalities in the digestive tract. If the nausea

and vomiting appear to be related to **anxiety**, stress, or an eating disorder, the doctor may refer the patient to a psychiatrist for further evaluation.

Treatment

Getting a breath of fresh air or getting away from whatever is causing the nausea can solve the problem. Eating olives or crackers or sucking on a lemon can calm the stomach by absorbing acid and excess fluid. Coke syrup is another proven remedy.

Vomiting relieves nausea right away but can cause **dehydration**. Sipping clear juices, weak tea, and some sports drinks help replace lost fluid and **minerals** without irritating the stomach. Food should be reintroduced gradually, beginning with small amounts of dry, bland food like crackers and toast.

Medications that are given to relieve nausea and vomiting are called **antiemetics**. Meclizine (Bonine), a medication for motion sickness, also diminishes the feeling of queasiness in the stomach. Dimenhydrinate (Dramamine), another motion-sickness drug, is not effective on other types of nausea and may cause drowsiness.

Newer drugs that have been developed to treat postoperative or postchemotherapy nausea and vomiting include ondansetron (Zofran) and granisetron (Kytril). Another treatment that has been found to lower the risk of nausea after surgery is intravenous administration of supplemental fluid before the operation.

Alternatives

Advocates of alternative treatments suggest **biofeedback**, **acupressure** and the use of herbs to calm the stomach. Biofeedback uses **exercise** and deep relaxation to control nausea. Acupressure (applying pressure to specific areas of the body) can be applied by wearing a special wristband or by applying firm pressure to:

- the back of the jawbone
- the webbing between the thumb and index finger
- the top of the foot
- the inside of the wrist
- the base of the rib cage

Acupuncture is another alternative treatment found to be effective in relieving nausea. A few people, however, experience nausea as a side effect of acupuncture.

Chamomile (*Matricaria recutita*) or lemon balm (*Melissa officinalis*) tea may relieve symptoms. Ginger (*Zingiber officinale*), another natural remedy, can be drunk as tea or taken as candy or powered capsules.

KEY TERMS

Acupuncture—A treatment technique associated with traditional Chinese medicine, in which thin needles are inserted into specific points located along energy channels in the human body known as meridians.

Antiemetic—A preparation or medication that relieves nausea and vomiting. Coke syrup, ginger, and motion sickness medications are examples of antiemetics.

Dehydration—Loss of fluid and minerals following vomiting, prolonged diarrhea, or excessive sweating.

Diabetic coma—Reduced level of consciousness that requires immediate medical attention.

Emesis—The medical term for vomiting.

Prevention

Massage, **meditation**, **yoga**, and other relaxation techniques can help prevent stress-induced nausea. Anti-nausea medication taken before traveling can prevent motion sickness. Sitting in the front seat, focusing on the horizon, and traveling after dark can also minimize symptoms.

Food should be fresh, properly prepared, and eaten slowly. Overeating, tight-fitting clothes, and strenuous activity immediately after a meal should be avoided.

Vomiting related to emotional upsets may be avoided by forms of **psychotherapy** that teach patients to manage stress in healthier ways.

Necrotizing enterocolitis

Definition

Necrotizing enterocolitis is a serious bacterial infection in the intestine, primarily of sick or premature newborn infants. It can cause the death (necrosis) of intestinal tissue and progress to blood **poisoning** (septicemia).

Description

Necrotizing enterocolitis develops in approximately 10% of newborns weighing less than two pounds (800 grams). It is a serious infection that can produce complications in the intestine itself—such as **ulcers**, perforations (holes) in the intestinal wall, and tissue necrosis—as well as progress to life–threatening septicemia. Necrotizing enterocolitis most commonly affects the lower portion of the small intestine (ileum). It is less common in the colon and upper small bowel.

Causes and symptoms

The cause of necrotizing enterocolitis is not clear. It is believed that the infection usually develops after the bowel wall has already been weakened or damaged by a lack of oxygen, predisposing it to bacterial invasion. Bacteria proliferate in the bowel and cause a deep infection that can kill bowel tissue and spread to the bloodstream.

Necrotizing enterocolitis almost always occurs in the first month of life. Infants who require **tube feedings** may have an increased risk for the disorder. A number of other conditions also make newborns susceptible, including **respiratory distress syndrome**, congenital heart problems, and episodes of apnea (cessation of breathing). The primary risk factor, however, is **prematurity**. Not only is the immature digestive tract less able to protect itself, but premature infants are subjected to many stresses on the body in their attempt to survive.

Early symptoms of necrotizing enterocolitis include an intolerance to formula, distended and tender abdomen, **vomiting**, and blood (visible or not) in the stool. One of the earliest signs may also be the need for mechanical support of the infant's breathing. If the infection spreads to the bloodstream, infants may develop lethargy and fluctuations in body temperature, and may periodically stop breathing.

Diagnosis

The key to reducing the complications of this disease is early suspicion by the physician. A series of x-rays of the bowel often reveals the progressive condition, and blood tests confirm infection.

Treatment

Over two–thirds of infants can be treated without surgery. Aggressive medical therapy is begun as soon as the condition is diagnosed or even suspected. Tube feedings into the gastrointestinal tract (enteral **nutrition**) are discontinued, and tube feedings into the veins (**parenteral nutrition**) are used instead until the condition has resolved. Intravenous fluids are given for several weeks while the bowel heals.

Some infants are placed on a ventilator to help them breathe, and some receive transfusions of platelets, which help the blood clot when there is internal bleeding. **Antibiotics** are usually given intravenously for at least 10 days. These infants require frequent evaluations by the physician, who may order multiple abdominal x rays and blood tests to monitor their condition during the illness.

Sometimes, necrotizing enterocolitis must be treated with surgery. This is often the case when an infant's condition does not improve with medical therapy or there are signs of worsening infection.

Surgical treatment depends on the individual patient's condition. Patients with infection that has caused serious damage to the bowel may have portions of the bowel removed. It is sometimes necessary to create a substitute bowel by making an opening (**ostomy**) into the abdomen through the skin, from which waste products are discharged temporarily. But many physicians avoiding this procedure and operate to remove diseased bowel and repair the defect at the same time.

Postoperative complications are common, including wound infections and lack of healing, persistent **sepsis** and bowel necrosis, and a serious internal bleeding disorder known as disseminated intravascular coagulation.

Prognosis

Necrotizing enterocolitis is the most common cause of death in newborns undergoing surgery. The average mortality is 30–40%, even higher in severe cases.

Early identification and treatment are critical to improving the outcome for these infants. Aggressive nonsurgical support and careful timing of surgical intervention have improved overall survival; however, this condition can be fatal in about one–third of cases. With the resolution of the infection, the bowel may begin functioning within weeks or months. But infants need to be carefully monitored by a physician for years because of possible future complications.

About 10–35% of all survivors eventually develop a stricture, or narrowing, of the intestine that occurs with healing. This stricture can create an intestinal obstruction that will require surgery. Infants may also be more susceptible to future bacterial infections in the gastrointestinal tract and to a delay in growth. Infants with severe cases may also suffer neurological impairment.

KEY TERMS

Enteral nutrition—Liquid nutrition provided through tubes that enter the gastrointestinal tract, usually through the mouth or nose.

Necrosis—The death of cells, a portion of tissue, or a portion of an organ due to permanent damage of some sort, such as a lack of oxygen supply to the tissues.

Parenteral nutrition—Liquid nutrition provided through tubes that are placed in the veins.

Sepsis—The presence of pus–forming or other disease–causing organisms in the blood or tissues. Septicemia, commonly known as blood poisoning, is a common type of sepsis.

The most serious long-term gastrointestinal complication associated with necrotizing enterocolitis is short-bowel, or short-gut, syndrome. This term refers to a condition that can develop when a large amount of bowel must be removed, making the intestines less able to absorb certain nutrients and enzymes. These infants gradually evolve from tube feedings to oral feedings, and medications are used to control the malabsorption, **diarrhea**, and other consequences of this condition.

Prevention

In very small or sick premature infants, the risk for necrotizing enterocolitis may be diminished by beginning parenteral nutrition and delaying enteral feedings for several days to weeks.

Some authorities have suggested that breast milk provides substances that may be protective, but there is no evidence that this practice reduces the risk of infection. A large multicenter trial showed that steroid drugs given to women in preterm labor may protect their offspring from necrotizing enterocolitis.

Sometimes necrotizing enterocolitis occurs in clusters, or outbreaks, in hospital newborn (neonatal) units. Because there is an infectious element to the disorder, infants with necrotizing enterocolitis may be isolated to avoid infecting other infants. Persons caring for these infants must also employ strict measures to prevent spreading the infection.

Neonatal care

Definition

Neonatal care refers to the care given to a newborn infant from the time of delivery through about the first month of life. The term *neonate* is used for the newborn infant during this 28–30 day period.

Description

Neonatal care begins as soon as the baby is born. In fact, suctioning of the nose and mouth may take place as the baby is in the process of being delivered—with the head out and while the mother is taking a pause before the next push. *In utero* the infant is swimming in amniotic fluid. As the baby comes down the birth canal, the contractions exert pressure on the body and push some of the amniotic fluid out of the lungs. It is this fluid that is suctioned out during those first few moments. Shortly after delivery, the umbilical cord is clamped and then cut. Shortly after clamping, the cord is checked for the presence of two arteries and one vein. Once the cord is clamped, the baby must breathe and function independently from the mother. The first few breaths cause several internal changes to occur.

A baby is very wet when born from being in its mother's womb. Drying the baby off right away is critical, because the baby can lose considerable body heat through evaporation, convection, radiation, and conduction. This is especially true of the head, which has a large surface area in relation to the rest of the body. Also, head hair retains considerable moisture if not well dried. A cap placed on the head once it has been dried helps to maintain body temperature. The nurse may place the newborn on the mother's skin while drying the skin, both to begin the bonding process and to allow the mother's body heat to warm the infant. The rubbing that takes place to dry the infant provides tactile and sensory stimulation. The neonate may cry, bringing more oxygen into the lungs. A certain amount of pressure is needed in the heart and lungs to convert from fetal circulation to neonatal circulation. A color change is noticeable as the infant's skin becomes less bluish and pinker in tone. In some circumstances, oxygen from a mask may be placed near the infant's mouth during dying off to increase the initial intake of oxygen. Once dry, the infant is wrapped in several warm receiving blankets and may be placed at the mother's breast for an initial **breastfeeding**. If the mother will not be breastfeeding, she may choose to hold the newborn at this point.

The first breastfeeding helps to trigger the involution process of the uterus, as it stimulates the production of natural oxytocin, which helps the uterus contract. Also, in the first hour or so after birth, the neonate is usually quite alert, unless the mother was given **pain** medications late in labor.

While the infant is being dried off, the mother is delivering the placenta. The amniotic fluid is clear, perhaps tinged with blood. If it appears murky in any way, the baby most likely had a bowel movement during the stressful labor and delivery process. This first bowel movement is called meconium. If present in the amniotic fluid, it is possible that the infant inhaled some into its lungs. This is called meconium aspiration. The neonate with meconium in the amniotic fluid may be intubated to avoid aspiration. Meconium aspiration can lead to tachypnea (rapid respirations) and also **pneumonia** and may require the neonate to spend some time under observation in the neonatal intensive care unit (NICU), instead of being kept with its mother. As the infant is being suctioned, assessed, and dried, it may be placed in a slight Trendelenburg position, depending on the hospital. This downward slant of about 10 degrees allows gravity to assist in draining mucus.

At one minute and five minutes after birth the neonate is assessed for Apgar scores. The infant's heart rate, respiratory effort, muscle tone, reflex, irritability, and color are each given a score of 0, 1, or 2. Each score is then added together for a highest

possible score of 10. The normal range is 7–10. It is rare to receive a 10, as some **cyanosis** in the hands and feet (called **acrocyanosis**) is quite normal.

In the birthing room a rapid **physical examination** is performed to assess any gross abnormalities as well as any heart-related problems and to determine the need for any immediate intervention. The spine is assessed and should be free of any openings or dimpling. It will be flat, as the lumbar and sacral curves develop later when the child learns to sit and walk. A more detailed examination takes place about 24 hours later. The umbilical cord and placenta are examined for any abnormalities. Any medications given to the mother during labor and delivery are recorded in the neonate's chart, as the medication could affect the infant's respirations and its own ability for tissue oxygenation. The physician or nurse-midwife also make sure the entire placenta has been expelled to avoid the risk of infectionfor the mother from any retained tissue.

Because the neonate has difficulty maintaining its temperature, any examination that is immediately needed usually takes place under a heat source. During the first 24 hours the neonate is adjusting to life outside the womb, and some normal fluctuations are expected. It is for this reason that the more thorough examination takes place a bit later on, once the newborn's systems stabilize.

Before leaving the delivery room the nurse will:

- place an identification band on the neonate's hands and feet
- place an ID band with the same number as the baby's on the mother's (and in some hospitals) on the father's wrist
- take a foot print of the infant (in some hospitals)
- give an intramuscular (IM) injection of vitamin K to the neonate
- administer an antibacterial eye ointment into both eyes

To assist the ability of the neonate's blood to clot, infants receive an IM injection of **vitamin K** in the delivery room. The injection is usually given in the thigh muscle, the largest and safest muscle in which to give an infant an injection. The antibacterial eye ointment used prevents contracting a possible infection from the birth canal, such as **gonorrhea** or chlamydia.

Hospitals differ in which identification system they use, but the premise is the same: before the infant leaves the delivery room, the baby should receive an ID band with a number on it. The same ID number is on a band for the mother, as well as possibly for the father. Before leaving the baby with the parents, the bands should be checked by the nurse or nursing student to avoid any mix-up. Some hospital ID bands contain a microchip that causes an alarm bell to ring if the infant is taken out of a certain area. Also, some hospitals require that if the mother is going to take a nap or a shower, the infant must be returned to the nursery so that the infant is not unattended in the mother's room. Some hospitals use a band on each of the baby's hands and feet, so that if one or two fall off, proper ID still remains on the neonate. In addition to the ID band, a print of the infant's foot is made along with the mother's fingerprint. Both are recorded on the same sheet of paper.

If the neonate appears physiologically unstable, the baby is taken either to the nursery or to the NICU for further evaluation or treatment. Once the mother's condition is stable, she may be wheeled to the infant's location if she desires.

Weight and length are measured, either in the birthing room or in the newborn nursery, and the vital signs are closely monitored and skin color is assessed for signs of **jaundice**. Jaundice that appears in the first 24 hours is of a different nature than that which sets in after 24 hours. If undressed, the infant is kept under radiant heat to assist in maintaining proper body temperature. Temperature may be regulated for several hours with a monitor attached to the chest skin. A rectal temperature may be taken to check for a patent anus. After any examinations, the infant is swaddled in several layers of receiving blankets, a cap is placed on the head to further reduce loss of body heat, and the newborn is placed in a bassinette either on its side, with a rolled blanket behind the back to prevent tipping, or on its back. To prevent **sudden infant death syndrome** (SIDS), infants should not be placed on their stomach.

Most insurance plans allow hospital stays of only 48 hours after an uncomplicated vaginal delivery, so much takes place within that time. Twenty-four to 72 hours after the neonate's first intake of protein, the baby's blood is checked via a heel-stick for the presence of **phenylketonuria** (PKU), a protein metabolism disorder that requires strict nutritional guidelines for treatment to avoid central nervous system (CNS) damage. Neonates whose mothers had **gestational diabetes** will have their blood sugar monitored in the nursery. During the second day of life the infant has a detailed physical assessment done cephalocaudal (head-to-toe). Parents who wish to have their male infants circumcised in the hospital make those arrangements. The nursery nurses monitor the circumcised infant for any signs of infection or abnormal bleeding. Newborns

WWW.BOOKBAZ.IR

usually receive a **hepatitis B vaccination** before leaving the hospital to prevent infection with the virus, which can cause serious liver damage.

Hospitals may differ in how much time the infant spends with the mother in her room. The aim is for a balance between the mother's need for rest to ensure more rapid healing, the need for the parents and baby to form a strong bond, and the safety of the infant if unattended. Most hospitals bring the breastfeeding infant to the mother on demand. Formula-fed babies may spend more time in the nursery with staff feeding the baby, if the mother needs more rest time after a difficult delivery.

Purpose

The purpose of neonatal care in the delivery room and newborn nursery is to accomplish the following:

- assess and evaluate the newborn as the baby transitions from intrauterine life (life in the womb) to life outside the womb
- evaluate and monitor the newborn's body systems for normal or abnormal functioning, helping to maintain normal functions and treat abnormal ones
- help parents bond with their infants
- provide a safe environment at all times

Results

The clamping of the umbilical cord signals the neonate's abrupt transition from intrauterine to extrauterine life. *In utero* the fetus's blood was oxygenated through the placenta and the mother's circulation. Now the neonate's lungs must take over. With the first breath, the lungs expand and create a pressure difference in the chest, pulmonary artery, and heart. This leads to the closing of the *ductus arteriosus* and the *foramen ovale*. The blood flow through the cord stops and any blood within the cord will clot, causing the vessels to dry out, allowing the cord to fall off within about 10 days. Assessment of the cord area can be done with each diaper change. The cord site should remain dry, with no evidence of redness, bleeding, or discharge.

Infants born by **cesarean section** do not have the force of the birth canal pushing amniotic fluid from the lungs. Some infants may have initial difficulty with respiration because excess remains in their lungs.

During the first hour after birth, the neonate is very alert. He or she may be interested in nursing or may spend time just gazing at the mother or parents. The initial breastfeeding establishes the neonate's ability to coordinate breathing, sucking, and swallowing.

Variability is normal in the newborn, so pulse and respirations should be monitored for an entire minute. If abnormal values are noted, yet the infant does not appear in distress, the attendant will wait a minute or two and then recheck. Normal values for the neonate include:

- Apical pulse (recorded over the heart) between 120 and 160. The sleeping newborn may have a pulse of 100, the crying infant may have a pulse of 180. Rates below 100 and above 180 should be investigated.
- Respirations range from 30 to 60 breaths per minute. Infants are nose-breathers, so a clear nasal passage is critical. Poor breastfeeding position can block the nose and requires repositioning. Respirations can be counted by watching the abdomen move up and down. While short periods of crying can be beneficial in bringing more oxygen into the lungs, long periods of crying exhaust the neonate's cardiovascular system and should be avoided.
- The average weight of a newborn is 7.5 pounds (3.4 kg), with a normal range of 5.5 to 8.5 pounds (2.5–3.8 kg). A weight above 10 pounds (4.5 kg) may indicate that the mother had gestational diabetes. The average length of the newborn is 20–21 inches (50-53 cm).
- Initially the newborn is very sensitive to temperature changes, as the ability to regulate body temperature is not yet well developed. A normal rectal temperature ranges from 97.8–99°F (36.5–37.2°C). A newborn suffering heat loss will have increased respirations.
- Within the first 24 hours, the newborn should void and pass meconium, a sticky, tar-like first stool. The neonate does not take in a great deal within the first few days, but intake and output should increase after the first few days. Bowel sounds are present.

A head-to-toe assessment is usually done without the parents present but can be very helpful if done in front of the first-time parent for reassurance. The head will appear large in relation to the body. Average head circumference is about 13.5 to 14 inches (34-35 cm). A circumference of less than 33 cm or greater than 37 cm may indicate a neurological abnormality and warrants further evaluation. The head of a baby born vaginally may look misshapen at first. This is called molding. The baby's skull allows for movement so that it can pass through the birth canal. Within a few days it takes on its normal shape. Infants delivered with the help of forceps or vacuum aspiration may have bruising on the head or even a cephalhematoma. Cephalhematoma is a collection of blood under the scalp, such as can result from blood vessels that have ruptured during birth. It does not cross the midline of the skull. Caput succedaneum is an area of **edema** under the

scalp. It may cross the midline. These will resolve over time, although the increased amount of blood being processed from the cephalhematoma may result in jaundice. Infants born by cesarean delivery have normally shaped heads right at birth if it is a scheduled cesarean delivery. If the mother has been in prolonged labor and a cesarean delivery is deemed necessary, the newborn's head may still be molded. Newborns may have a full head of hair, although most often falls out during the first month. The two soft spots on top of the head are called fontanels. The anterior fontanel should close after 12 to 18 months; the smaller, posterior fontanel should close by the third month. A bulging fontanel in a quiet infant indicates increased intracranial pressure. A depressed fontanel indicates **dehydration**. It is normal to be able to feel the pulsing of each heart contraction at the anterior fontanel. The eyes and ears should be in good proportion. Low-set ears indicate a chromosomal abnormality, such as trisomy 13 or 18. The nose, which is large at this age for the face, may have little white dots called milia. These are blocked sebaceous glands and will disappear in a few weeks. These should not be squeezed or scratched, to avoid creating a portal for infection. The mouth should have an intact palate. Small round dots may be present and are called Epstein pearls. They are a form of **calcium** deposit and will disappear. Parents may confuse them with white patches of thrush, which is a Candida infection.

Newborn skin may be somewhat mottled, and early acrocyanosis in the hands and feet is common. Central cyanosis in the trunk should be investigated, as it indicates decreased oxygenation. Jaundice that sets in after the first 24 hours is common, but the bilirubin level should be closely monitored if the jaundice travels below the nipple line. **Birthmarks**, or hemangiomas, are common. Some are flat and reddish-purple in color. They may fade or disappear over time, but some larger ones may remain. Laser treatment in later life is quite common to remove those marks that are large or prominent enough to interfere with an individual's self-esteem. Raised, cavernous hemangiomas may indicate similar lesions on internal organs that can rupture and bleed with a blow to the child's abdomen.

Newborns may be covered in vernix caseosa, a waxy substance that acts as a skin lubricant. It is especially noticeable in skin folds. Babies born post-dates (over 40 weeks) have very dry skin and may have cracks in the skin folds. The color of the vernix is an indicator of intrauterine life. It may be green-tinged, indicating the presence of meconium in the amniotic fluid. Yellow vernix indicates bilirubin. Lanugo is a fine, downy hair that may cover the shoulders, back, and upper arms. Premature infants have more lanugo; post-dates infants usually have none at all. The neonate's skin is sensitive and may respond to washing products with a rash.

The hormones circulating in the mother are passed into the fetus. Newborns may have enlarged genitalia in response to the circulating maternal hormones. Female neonates may have some white or blood-tinged discharge from the vagina for a week or so after birth. There should be no evidence of **trauma**, however.

The neonate is able to move arms and legs symmetrically. Lack of movement or limpness indicates an injury and needs careful evaluation. A broken clavicle may be the result of a difficult birth, but should heal to full movement. The examiner will check for extra digits or fused/webbed digits. The legs are normally bowed at this time and will straighten with growth. Feet may appear twisted, due to a long-held intrauterine position. If they can be easily brought into alignment, this will usually revert to normal with growth and weight bearing. A foot that does not come into alignment may indicate talipes, or **clubfoot**. Early treatment brings the best success. The hips are checked for symmetrical abduction. Clicking heard during examination may indicate subluxation, and treatment is usually begun right away.

Neonatal reflexes are checked to assess for any neuromuscular abnormalities. Intact reflexes provide a safety/survival mechanism for the newborn. These reflexes include:

- Rooting; present from birth until about six weeks of age. Stroking the corner of the mouth elicits the reflex. The neonate should turn his or her head in that direction. This reflex assists the infant in finding the breast.
- Sucking; from birth until about six months of age. Touching the lips begins the sucking reflex. When the lips are touched by the breast or bottle nipple, the infant begins to suck, taking in nourishment.
- Swallowing; as food reaches the back of the tongue, the swallowing reflex is elicited and the food is swallowed.
- Palmar grasp; disappears by three months of age. Placing an object, such as a finger, into the neonate's palm elicits this reflex. The infant will grasp tightly onto whatever has been placed into her hand.
- Stepping; present from birth until about three months of age. Holding the infant upright with his feet just touching a flat surface causes the infant to

WWW.BOOKBAZ.IR

KEY TERMS

Acrocyanosis—The slight cyanosis of the hands and feet of the neonate, considered normal and due to an immature circulatory system, which is still in flux.

Ductus arteriosus—The ductus arteriosus, a vessel connecting the pulmonary artery to the aorta in the fetus. After birth, this begins to constrict, and the neonate's blood now leaves the heart via the pulmonary artery, going into the lungs to be oxygenated. Once fully constricted it becomes a ligament.

Foramen ovale—The foramen ovale, a fetal cardiac structure that allows the blood in both upper chambers (atria) of the heart to mix. After birth, the pressure rises in the left atrium pushing this opening closed, allowing the heart to function in a two-sided fashion: the right side carries the unoxygenated blood to the lungs, and the left side pumps the oxygenated blood out into the body.

Trendelenburg—In the Trendelenburg position, the body at a slant with the head below the heart. For suctioning purposes, the neonate is placed in a slight Trendelenburg position, of about 10 degrees. This allows the force of gravity to assist in expelling amniotic fluid and mucous.

take small weight-bearing steps. These are not true steps, and the infant must be fully supported.

- Babinski; present until about three months of age. Stroking the sole of the neonate's foot, starting at the heel, should start the reflex. The newborn will curl and fan his toes upward and outward. Once the reflex disappears, the same motion should cause the toes to flex, as in most adults.
- Moro; strongest from birth through two months of age, then fades until it disappears around the fifth month. This is a startle reflex, so evaluation is done somewhat gently. One method is for the examiner to clap the hands near the newborn, but out of eyesight. Another method is to hold the infant above a padded mat, then either let the head fall backwards by an inch or so, or quickly lower the infant's body toward the mat. This gives the infant a sense of falling. The reflex action is for the neonate first to extend both arms and legs, then to pull the legs up toward his abdomen while making the shape of a "C" with his fingers.

A neonate's hearing and vision will be assessed. The fetus is able to hear inside the uterus, and after birth it will clearly respond to the voices of the mother and father but may ignore unfamiliar voices. The neonate focuses best on an object 9–12 inches (23–30 cm) away. This is approximately the distance between its face and the face of the mother when held in a breastfeeding position. There should be no redness or drainage from the eye on inspection. The blink reflex should be intact, elicited by briefly shining a bright light at the eye. Depending on the birthing position, there may be edema around the eye, although this fluid should reabsorb in a few days after birth.

Neonatal care continues through about the fourth week after birth. During this time the infant and mother may receive a home nursing visit to ensure that breastfeeding is well established, that no jaundice is present in the neonate, and that the mother is healing well from the delivery. At the follow-up office visit, the nurse or medical assistant will weigh and measure the length of the infant.

Patient education

Parent education, especially for the first-time parent, is extremely important. Nurses or nurse-midwives provide breastfeeding and postpartum teaching for the mother, as well as explain the care needed for the newborn. This may include cord care, normal number of daily feedings and diapers, how to determine the presence of jaundice, and how and when to bathe the infant. The attendant will answer any questions the new parents may have. A follow-up appointment is usually established before the infant leaves the hospital. The nurse will often be the one to ensure that a car seat is present and properly installed in the car before allowing the mother and baby to leave the hospital, as mandated by state law. Nurses also provide information when parents call with questions to the doctor's office.

Neonatal jaundice

Definition

Neonatal **jaundice** refers to the yellow discoloration of the skin and sclera (whites) of the eyes in newborns, which results as the breakdown of bilirubin goes faster than the rate at which it can leave the body, causing its level to rise in the blood.

A newborn baby undergoes phototherapy with visible blue light to treat his jaundice. *(Cindy Roesinger/ Photo Researchers, Inc.)*

Demographics

Neonatal jaundice is extremely common. In the United States, it is the most common condition needing medical care in newborns. The incidence of neonatal jaundice varies with location and ethnicity. It is highest in those of East Asian, American Indian, and Greek descent. The condition is more common in white than in black babies, and the rate is increased in infants of mothers at high altitudes. Preterm babies have a higher rate of neonatal jaundice than full-term babies.

Description

Neonatal jaundice and hyperbilirubinemia are terms used when a newborn has a higher-than-normal level of bilirubin in the blood. Bilirubin is an end product of the breakdown of the hemoglobin present in the red blood cells at the end of their life cycle. Hemoglobin carries oxygen to tissues and cells. Before birth the placenta is not as efficient in providing oxygen as the baby's lungs will be after birth. Because of this, infants *in utero* have more red blood cells than they will need after birth to provide enough oxygen. Therefore, newborns have an excess of red blood cells that they need to process and an immature liver with which to complete the job.

When the fetus is *in utero*, bilirubin is processed through the placenta and the maternal-fetal circulation. After birth, the infant's often-immature liver must take over this task. Clinical jaundice (serum bilirubin levels of 5–7 mg/dL and above) occurs in about 60-70% of term newborns and about 80% of premature infants. Ever since hospital stays after delivery decreased to 24–48 hours postpartum, hyperbilirubinemia has become the leading cause of hospital re-admissions in the first two weeks of life. The greatest concern with hyperbilirubinemia is that the unexcreted bilirubin will begin to deposit in the brain of the newborn, resulting in a serious, potentially life-threatening condition called kernicterus. Kernicterus occurs in about 1.5 of every 100,000 live births in the United States. Another term used for kernicterus is brain **encephalopathy**.

Causes and symptoms

An elevated bilirubin level may be due to its increased production, a decreased rate of conjugation, or abnormalities of the liver. In order for the bilirubin to be excreted in the urine and stool, it must be converted, or conjugated, from a fat- or lipid-soluble form to a water-soluble form. Bilirubin that has not been excreted can be reabsorbed and contributes to increased blood levels.

Initial symptoms of a rising bilirubin level can be subtle, and usually include increased drowsiness, which leads to poor feeding, and the subsequent decreased urine and stool output. The diaper may contain orange spots, an indication of the presence of uric acid crystals, a sign of **dehydration**. A change in the infant's cry to a high-pitched tone may indicate early neurological damage.

There are several types of jaundice. Jaundice that sets in within the first 24 hours after birth is usually due to an Rh factor or ABO blood incompatibility between the mother and infant.

WWW.BOOKBAZ.IR

The most common form of neonatal jaundice appears between the first 24 and 72 hours after birth and is usually considered a benign form. It is often referred to as early-onset breast milk jaundice, and is related to insufficient **breastfeeding**, which results in decreased nutritional intake and decreased stool production. With decreased stool volume, the bilirubin in the stool is not adequately excreted, and remains available for reabsorption. Increasing feedings from six to 12 times a day, and checking for latching-on and a good sucking and swallowing patterns, can lead to a decreasing bilirubin level to within normal limits. To encourage adequate maternal milk production, infant supplementation with water or glucose is discouraged.

Late-onset breast milk jaundice may occur in 10–30% of breast-fed infants and appears in the second to sixth weeks of life. This form of jaundice is believed to be related to a substance present in the mother's milk that affects the infant's absorption of bilirubin.

Risk factors

Risk factors for the development of hyperbilirubinemia include:

- premature birth
- East Asian and Native American descent
- maternal diabetes
- hemolytic disease in the neonate
- sepsis
- family history of jaundice
- presence of excessive bruising due to traumatic birth, and cephalhematoma
- oxytocin-induced delivery
- mother's use of sulfa medications during pregnancy
- history of familial liver disease
- delayed cord clamping
- thyroid gland abnormalities
- G6PD (glucose-6-phosphate dehydrogenase) deficiency

Diagnosis

Examination

Diagnosis of hyperbilirubinemia usually begins with the observation of jaundice at the time of **physical examination**. However, a delay in recognition of jaundice may occur since many infants have already gone home before its onset. Pediatric practices vary as to times of follow-up after hospital discharge. Parents may call their pediatric care provider's office because of jaundice, or because of a decreased ability of the infant to feed. Examination of the infant is best done next to a window so that the jaundice can be assessed in natural light.

KEY TERMS

Bilirubin—A yellowish-brown substance in the blood that forms as old red blood cells are broken down.

Jaundice—a condition in which bilirubin, a waste product caused by the normal breakdown or red blood cells, builds up in the body faster than the liver can break it down. People with jaundice develop yellowish skin and the whites of their eyes become yellow. The condition can occur in newborns and people with liver damage.

Kernicterus—A serious condition in which bilirubin deposits in the brain leading to permanent neurological damage and potentially death.

Tests

Blood tests to check the bilirubin level, blood type, and for signs of dehydration will usually be ordered. Blood is drawn by a heel stick. Heel sticks on an infant can be difficult when the infant is dehydrated. Ways to facilitate a more successful blood draw include:

- Use of a heel warmer to increase circulation to the foot.
- Having a parent hold the infant in a seated position so that the foot is below the level of the heart.
- Having the parent feed the infant prior to the lab visit.

Treatment

Treatment is primarily focused on decreasing the bilirubin level to prevent the progression of the condition to kernicterus. In kernicterus, the bilirubin deposits in the brain. This extreme condition leads to central nervous system damage and can progress to **hearing loss**, seizures, and death.

Phototherapy

For many infants, increasing breastfeeding will be sufficient to bring about adequate hydration and an increase in gastric motility and the amount of stool, so that the bilirubin is effectively excreted from the body. Some infants may need the additional assistance of **phototherapy**. The light source most effective in

treating hyperbilirubinemia occurs in the blue-green spectrum. Phototherapy may be provided in the hospital. In the hospital the infant is usually placed in a special bassinet, with an overhead light source. The skin is uncovered, exposing as much surface area to the light. The infant's eyes and genitals are usually shielded from direct light and heat, depending on the intensity of the light.

If the bilirubin level is under about 15–20 mg/dL, phototherapy may be administered via a fiberoptic source referred to as a blanket or belt in the home. The home unit is designed to encourage parent-infant bonding. The blanket/belt wraps around the infant's bare middle so that the cool light source is next to the skin. There is no need to shield the eyes from the light, and parents can hold, feed, and interact with the infant as usual. Most insurance companies cover the cost of the home rental for the phototherapy equipment and the accompanying daily home nursing visits.

In 1994 the American Academy of Pediatrics (AAP) developed guidelines for care and management of neonatal jaundice. These guidelines were reviewed and updated in 2004. In studies where experienced pediatric practitioners evaluated the same infants for jaundice, considerable discrepancies existed. Despite all the research done in this area, there are no consistent predictors of which infants will continue from benign jaundice to kernicterus. Research studies express concern over finding a balance between treating those that need treatment without treating well infants unnecessarily.

Prognosis

Jaundice addressed in its early stages rarely progresses to kernicterus, and therefore the prognosis for complete resolution of the problem is excellent. Phototherapy is extremely effective in bringing down the bilirubin levels. Some extreme cases may require a blood **transfusion**, but those situations are relatively rare. Infants who do develop kernicterus may continue to have long-term neurological effects present if the kernicterus was well established at the time of initiation of treatment.

Prevention

Primary prevention begins with addressing the risk factors mentioned previously. Prevention of kernicterus requires early detection, monitoring and potential treatment of jaundice with rising bilirubin levels. Frequent feedings of ten or more per day help to ensure adequate hydration, **nutrition**, gastric motility, and stool and urine output.

Nephrectomy

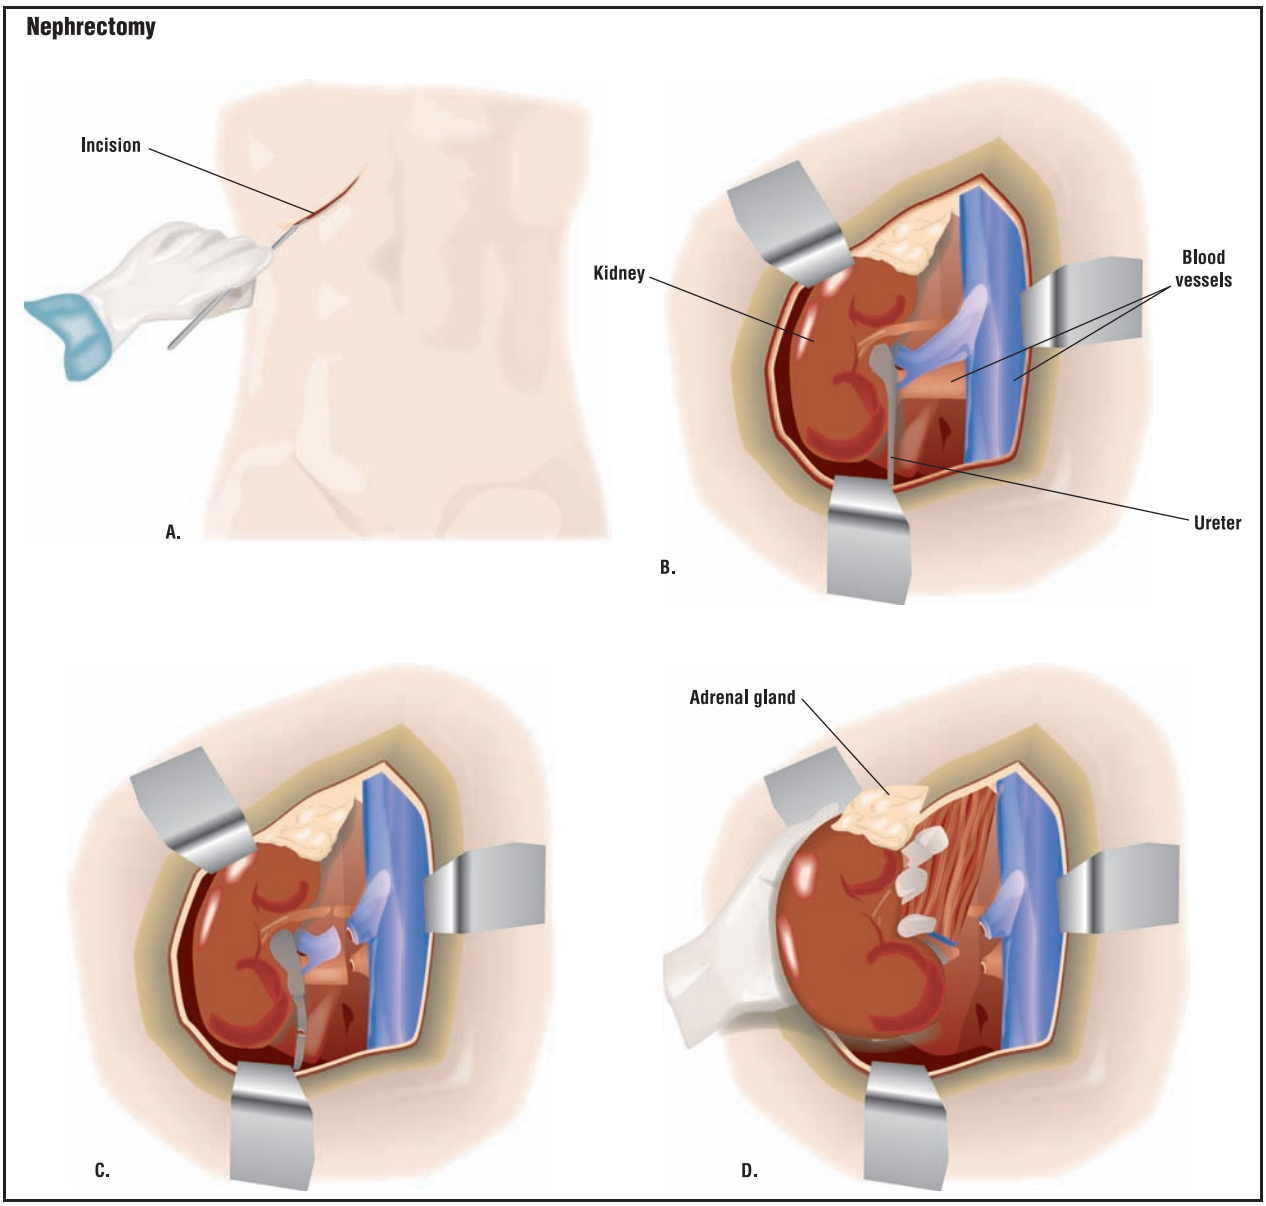
Definition

A nephrectomy is a surgical procedure for the removal of a kidney (radical nephrectomy) or a section of a kidney (partial nephrectomy, also known as nephron-sparing surgery).

Purpose

Nephrectomy, or kidney removal, is performed on patients with severe kidney damage from disease, injury, or congenital conditions. These include cancer of the kidney (renal cell carcinoma), **polycystic kidney disease**, **hydronephrosis** (kidney swelling), and serious kidney infections. It is also used to remove a healthy kidney from a donor for the purposes of **kidney transplantation**.

WWW.BOOKBAZ.IR



To remove a kidney in an open procedure, an incision is made below the rib cage (A). The kidney is exposed (B), and connections to blood vessels and the ureter are severed (C). The kidney is removed in one piece (D). *(Illustration by GGS Information Services. Copyright © Cengage Learning®.)*

Demographics

The HCUP Nationwide Inpatient Sample from the Agency for Healthcare Research and Quality (AHRQ) reports that 61,905 patients underwent partial or radical nephrectomy surgery for non-transplant-related indications in the United States in 2010. Patients with **kidney cancer** accounted for more than half of those procedures. About 65,150 new cases of renal cell carcinoma were expected to be diagnosed in 2013, per the American Cancer Society, as well as 13,680 kidney cancer–related deaths.

According to the United Network for Organ Sharing (UNOS), 5,622 people underwent nephrectomy to become living kidney donors in 2012. Of these, 2,107 were male and 3,515 were female. Related donors were more common than non-related donors, with full siblings being the most common relationship

between living donor and kidney recipients, and child to parent being the next most common relationship between living donor and kidney recipients. Nearly 3,000 new patients are added to the kidney waiting list each month.

Description

Nephrectomy may involve removing a small portion of the kidney or the entire organ and surrounding tissues. In partial nephrectomy, only the diseased or infected portion of the kidney is removed. Radical nephrectomy involves removing the entire kidney, a section of the tube leading to the bladder (ureter), the gland that sits atop the kidney (adrenal gland), lymph nodes, and the fatty tissue surrounding the kidney. A simple nephrectomy performed for living donor transplant purposes requires removal of the kidney and a section of the attached ureter. A nephrectomy may be performed as an open procedure or in some situations may be performed laparoscopically.

Open nephrectomy

In a traditional, open nephrectomy, the kidney donor is administered general **anesthesia** and a 6–10 in (15.2–25.4 cm) incision is made through several layers of muscle on the side or front of the abdomen. A rib resection may be necessary for access to the kidney and other structures. The blood vessels connecting the kidney to the donor are cut and clamped, and the ureter is also cut between the bladder and kidney and clamped. Depending on the type of nephrectomy procedure being performed, the ureter, adrenal gland, and/or surrounding tissue may also be dissected. The kidney is removed and the vessels and ureter are then tied off or sutured to achieve hemostasis. The incision is approximated and sutured (sewn up). The surgical procedure can take up to three hours, depending on the type of nephrectomy being performed.

Laparoscopic nephrectomy

Laparoscopic nephrectomy is a form of **minimally invasive surgery** that utilizes specialized instruments and endoscopic components to access, dissect, and remove the kidney. The surgeon views the kidney and surrounding tissue with a flexible endoscope. A trocar port is inserted into the abdomen to gain access. Pneumoperitoneum is established by inserting carbon dioxide into the abdominal cavity to inflate the cavity and improve visualization of the kidney and surrounding tissue. Additional trocar ports are inserted into the abdominal cavity for insertion of the instrumentation and camera components. The kidney and tissue are identified and dissected free. Hemostasis is achieved and the kidney is isolated. The kidney may be removed by morcellation or by securing it in a bag and pulling it through a trocar port. Although laparoscopic nephrectomy takes slightly longer than a traditional nephrectomy, it promotes a faster recovery time, shorter hospital stays, and reduced postoperative **pain**.

A modified laparoscopic technique called hand-assisted laparoscopic nephrectomy may also be used to remove the kidney. In the hand-assisted surgery, a small incision of 3–5 in (7.6–12.7 cm) is made in the patient's abdomen. The incision allows the surgeon to place his or her hand in the abdominal cavity using a special surgical glove that also maintains a seal for the inflation of the abdominal cavity with carbon dioxide. This technique gives the surgeon the benefit of using his or her hands to feel the kidney and related structures. The kidney is then removed by hand through the incision instead of with a bag.

Preparation

If nephrectomy is required for the purpose of kidney donation, it will be performed by a transplant surgeon in one of over 200 UNOS-approved hospitals nationwide. For patients with renal cell carcinoma, nephrectomy surgery is typically performed in a hospital setting by a surgeon specializing in urologic oncology.

Prior to surgery, blood samples will be taken from the patient to type and crossmatch in case a **transfusion** is required during surgery. A catheter will also be inserted into the patient's bladder. The surgical procedure will be described to the patient, along with the possible risks.

Aftercare

Nephrectomy patients may experience considerable discomfort in the area of the incision. Patients may also experience numbness, caused by severed nerves, near or on the incision. Pain relievers are administered following the surgical procedure and during the recovery period on an as-needed basis. Although deep breathing and coughing may be painful due to the proximity of the incision to the diaphragm, breathing exercises are encouraged to prevent **pneumonia**. Patients should not drive an automobile for a minimum of two weeks.

WWW.BOOKBAZ.IR

KEY TERMS

Hemostasis—Slowing down or stopping bleeding.

Hydronephrosis—Severe swelling of the kidney due to backup of urine. It may occur because of an obstruction, calculi, tumor, or other pathological conditions.

Morcellation—The division of tissue or tumors into smaller pieces.

Pneumoperitoneum—The presence of air or gas in a cavity.

Polycystic kidney disease—A hereditary kidney disease that causes fluid- or blood-filled pouches of tissue called cysts to form on the tubules of the kidneys. These cysts impair normal kidney function.

Renal cell carcinoma—Cancer of the kidney.

Trocar—A small sharp instrument used to puncture the abdomen at the beginning of the laparoscopic procedure.

Results

Normal results of a nephrectomy are dependent on the purpose of the procedure and the type of nephrectomy performed. Immediately following the procedure, it is normal for patients to experience pain near the incision site, particularly when coughing or breathing deeply. Renal function of the patient is monitored carefully after surgery. If the remaining kidney is healthy, it will increase its functioning over time to compensate for the loss of the removed kidney.

Length of hospitalization depends on the type of nephrectomy procedure. Patients who have undergone laparoscopic radical nephrectomy may be discharged two to four days after surgery. Traditional open nephrectomy patients are typically hospitalized for about a week. Recovery time will also vary, from three to six weeks on average.

Morbidity and mortality rates

Survival rates for living kidney donors undergoing nephrectomy are excellent; mortality rates are only 0.03% or three deaths for every 10,000 donors. Many of the risks involved are the same as for any surgical procedure—infection, hemorrhage, blood clot, or allergic reaction to anesthesia.

For patients undergoing nephrectomy as a treatment for renal cell carcinoma, survival rates depend on several factors, including the stage of the cancer and the patient's overall health and medical history. According to the American Cancer Society, the five-year survival rate for patients with stage I renal cell carcinoma is 81 percent, while the five-year survival rate for stage II kidney cancer is 74 percent. Stage III and IV cancers have metastasized, or spread, beyond the kidney and have a lower survival rate: 53 percent for stage III and about 8 percent for stage IV. **Chemotherapy**, radiation, and/or immunotherapy may also be required for these patients.

Risks

Possible complications of the nephrectomy procedure include infection, bleeding (hemorrhage), and postoperative pneumonia. There is also the risk of kidney failure in a patient with impaired function or disease in the remaining kidney.

Alternatives

Because the kidney is responsible for filtering wastes and fluid from the bloodstream, kidney function is critical to life. Nephrectomy candidates diagnosed with serious **kidney disease**, cancer, or infection usually have few treatment choices aside from this procedure. However, if kidney function is lost in the remaining kidney, the patient will require chronic dialysis treatments or transplantation of a healthy kidney to sustain life.

Nephritic syndrome *see* **Glomerulonephritis**

Nephritis

Definition

Nephritis is a medical condition involving the inflammation of the kidneys. The condition often times involves the glomerulus (a tubular structure that filters blood to form urine), the renal tubule (the portion of the nephron that contains tubular fluid filtered through the glomerulus), or the interstitial tissue surrounding the glomeruli and tubules. When inflammation of the glomeruli is involved, the condition is known as **glomerulonephritis**. Interstitial nephritis (also called tubule-interstitial nephritis) is the inflammation of the spaces between the kidney (renal) tubules.

Description

Nephritis occurs when the kidneys become inflamed. As this happens, they begin to leak red blood cells out of damaged glomeruli, which results in blood in the urine. Bloody urine is called proteinuria. As this condition progresses, essential proteins needed by the body are lost, which eventually can lead to life-threatening conditions. At this stage, blood begins to abnormally clot, possibly resulting in **stroke** and death.

The most prevalent form of acute nephritis is glomerulonephritis. This condition affects children and teenagers far more often than it affects adults. Glomerulonephritis is the inflammation of the glomeruli, or small, round capillary filters located in the kidneys. These capillaries transport blood and act as filtering agents for the kidneys. When these filters are damaged due to inflammation, they are unable to properly filter the blood.

Pyelonephritis is recognized as inflammation of the kidney and upper urinary tract. This inflammation begins in the bladder, travels up the ureters (the tubes that carry urine from the kidney to the urinary bladder), and spreads into the kidneys. It affects adults more than children.

A third type of nephritis is hereditary nephritis, a rare condition. Other types of nephritis are lupus nephritis (which is caused by **systemic lupus erythematosus** [SLE or lupus], a problem with the immune system) and athletic nephritis (which is caused by strenuous **exercise**, either in its duration or severity).

The spaces between the renal tubules can become inflamed in what is called interstitial nephritis. When this happens the kidneys swell, causing the kidneys to function improperly or not to function at all.

Certain people are at greater risk for contracting nephritis. These risks include having had recent surgery of the urinary tract or using excessive amounts of **antibiotics** or **pain** medicines.

Demographics

Nephritis is considered a serious medical condition throughout the world. It is often ranked as one of

WWW.BOOKBAZ.IR

the ten worst problems with respect to causing premature human death.

Causes and symptoms

Each type of nephritis has its own cause or set of causes. However, the cause of glomerulonephritis is unknown. Various conditions—such as a history of cancer, problems with the immune system, and abscesses that enter the kidneys—can encourage infections that lead to the condition.

Pyelonephritis usually occurs suddenly, and the acute form of this disease is more common in adult women. The most common cause of this form of bacterial nephritis is the backward flow of infected urine from the bladder into the upper urinary tract. This infection, commonly called **urinary tract infection**, sometimes reaches into the pyelum of the kidneys. Its symptoms include **fever** and chills, **fatigue**, burning or frequent urination, cloudy or bloody urine, and aching pain on one or both sides of the lower back or abdomen. *Escherichia coli* (commonly called *E. coli*), which is found in the intestines, is the bacteria that causes most cases of pyelonephritis.

Hereditary nephritis can be present at birth. The rare disease has many different forms and can be responsible for up to 5% of end-stage renal disease in men. An allergic reaction to a medicine or an antibiotic is one cause of interstitial nephritis. That reaction tells the body to fight against an entering foreign agent. When a medication is the cause, it is called acute interstitial allergic nephritis. Various antibiotics can cause interstitial nephritis, including ampicillin, methicillin, and penicillin. Other causes include:

- autoimmune disorders such as anti-tubular basement membrane disease, systemic lupus erythematosus, or Wegnener's granulomatosis
- excessive amounts of calcium or uric acid in the blood
- extended use of medications such as aspirin, acetaminophen (Tylenol), and nonsteroidal anti-inflammatory drugs (NSAIDs)
- insufficient potassium in the blood
- infections

Nephritis can also be caused by surgery on the bladder, kidneys, or ureters. Urinary examinations of the bladder can also cause nephritis, as can the formation of **kidney stones**.

The symptoms of nephritis vary depending on the type. The most commonly shared symptoms include:

- bloody urine or pus in the urine
- cloudy urine
- fever
- frequent urination; a need to urinate
- high blood pressure
- pain or a burning sensation during urination
- pain in the area of the kidneys or abdomen
- pelvic pain
- swelling on the body, especially in the face, feet, and legs
- vomiting

Acute glomerulonephritis usually develops a few weeks after a strep infection of the throat or skin. Symptoms of glomerulonephritis include fatigue, high blood pressure, and swelling. Swelling is most notable in the face, hands, ankles, and feet. A wide variety of symptoms can occur with interstitial nephritis, depending on its severity. Commonly observed symptoms include:

- decreased or increased urine output
- fever
- bloody urine
- nausea
- vomiting
- rash
- swelling of one or various body parts
- weight gain (caused by fluid retention)

The symptoms of lupus nephritis may include foamy urine, high blood pressure, and **edema** (usually swelling of the legs, ankles, or feet). Other symptoms include muscle pain, fever, joint pain or swelling, or red **rashes** (usually on the face).

Diagnosis

Diagnosis of nephritis is based on the following:

- the patient's symptoms and medical history
- physical examination, which may reveal abnormalities of the heart or lungs, high blood pressure, or fluid on the lungs
- biopsy, which involves the removal of a small piece of kidney tissue so that it can be examined under a microscope
- laboratory tests of blood and urine, which determine the presence and type of bacteria, signs of infection, and abnormal blood cells; common tests include arterial blood gases, blood chemistry, blood urea nitrogen (BUN) and blood creatinine levels, and complete blood count (CBC)

- imaging studies such as ultrasound, x ray, or computed tomography (CT) scans to determine blockage and inflammation

Urinalysis can reveal the presence of the following:

- albumin and other proteins
- red and white blood cells
- pus, blood, or bacteria in the urine

Treatment

Treatment of nephritis depends on the specific problem. For instance, treatment of glomerulonephritis normally includes drugs such as cortisone or cytotoxic drugs (those that are destructive to certain cells or antigens). **Diuretics** may be prescribed to increase urination. If high blood pressure is present, drugs may be prescribed to decrease the **hypertension**. Iron and vitamin supplements may be recommended if the patient becomes anemic.

Acute pyelonephritis may require hospitalization for severe illness. Antibiotics will be prescribed, with the length of treatment based on the severity of the infection. In the case of chronic pyelonephritis, a six-month course of antibiotics may be necessary to rid the infection. Surgery is sometimes necessary. Pain relievers may also be used. High blood pressure is often controlled with the use of **calcium channel blockers**.

Treatment of hereditary nephritis depends of the variety of the disease and severity at the time of treatment. Lupus nephritis is treated with medicines that suppress the immune system. Such medicines usually include a corticosteroid (most often prednisone), which helps to reduce inflammation in the kidney, along with an immunosuppressive medicine, such as cyclophosphamide or mycophenolate mofetil. Blood-pressure medicines may also be used to control hypertension (high blood pressure). Such drugs include angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). **Beta blockers**, **calcium** channel blockers, or other blood pressure medications may also be used in addition to ACE inhibitors or ARBs.

Alternatives

Alternative treatment of nephritis should be used as a complement to medical care and under the supervision of a licensed practitioner. Herbs thought to relieve symptoms of nephritis include cleavers (*Galium* spp.) and wild hydrangea.

Drinking extra amounts of water is highly recommended because water helps to flush waste products from the kidneys that may be delaying recovery of nephritis. Lower **sodium** consumption is also advised to prevent the retention of fluids.

KEY TERMS

Albumin—A member of a family of globular proteins, the most common of which is serum albumin.

Glomerulus—A tubular structure within the kidneys that filters blood to form urine.

Pyelum—Also called the renal pelvis, a funnel-like dilated proximal portion of the ureter within the kidneys.

Systemic lupus erythematosus (SLE)—Also called lupus, a systemic autoimmune disease that can damage many parts of the body, including the blood vessels, heart, joints, kidneys, liver, lungs, and skin.

Ureter—A tube consisting of smooth muscle fibers that sends urine from the kidneys to the urinary bladder.

Prognosis

Prognosis for most cases of glomerulonephritis is generally good. Ninety percent of children recover without complications. With proper medical treatment, symptoms usually subside within a few weeks or at the most a few months.

Pyelonephritis in the acute form offers a good prognosis if diagnosed and treated early. Follow-up urinalysis studies determine if the patient remains bacteria-free. If the infection is not cured or continues to recur, it can lead to serious complications such as **bacteremia** (bacterial invasion of the bloodstream), hypertension, chronic pyelonephritis, and even permanent kidney damage.

If hereditary nephritis is not detected or treated, it can lead to complications such as eye problems, deafness, or kidney failure. Most cases of interstitial nephritis are short-term in nature and minor in severity. However, occasionally, the condition can cause permanent problems such as **chronic kidney failure**.

Prevention

Streptococcal infections that may lead to glomerulonephritis can be prevented by avoiding exposure to strep infection and obtaining prompt medical treatment for **scarlet fever** or other infection.

WWW.BOOKBAZ.IR

Pyelonephritis can best be avoided if those with a history of urinary tract infections take care to drink plenty of fluids, urinate frequently, and practice good hygiene following urination. Hereditary nephritis cannot be prevented, but research to combat the disease continues.

Nephrotic syndrome

Definition

Nephrotic syndrome is a collection of symptoms that occur because the tiny blood vessels (the glomeruli) in the kidney become leaky. This allows protein (normally never passed out in the urine) to leave the body in large amounts.

Description

The glomeruli (a single one is called a glomerulus) are tiny tufts of capillaries (the smallest type of blood vessels). Glomeruli are located in the kidneys, where they allow a certain amount of water and waste products to leave the blood, ultimately to be passed out of the body in the form of urine. Normally, proteins are unable to pass through the glomerular filter. Nephrotic syndrome, however, occurs when this filter becomes defective, allowing large quantities of protein to leave the blood circulation and pass out of the body in the urine.

Demographics

Patients with nephrotic syndrome are from all age groups, although in children children between the ages of 18 months and four years have an increased risk of the disorder. In children, boys are more frequently affected; in adults, the ratio of men to women is closer to equal.

Causes and symptoms

Nephrotic syndrome can be caused by a number of different diseases. The common mechanism that seems to cause damage involves the immune system. For some reason, the immune system becomes directed against the person's own kidney. The glomeruli become increasingly leaky as various substances from the immune system are deposited within the kidney.

A number of different kidney disorders are associated with nephrotic syndrome, including:

- minimal change disease or MCD (responsible for about 80% of nephrotic syndrome in children, and about 20% in adults), which is a disorder of the glomeruli
- focal segmental glomerulosclerosis (FSGS)
- membranous glomerulonephritis (MGN)
- membranoproliferative glomerulonephritis (MPGN)

Other types of diseases can also result in nephrotic syndrome. These include diabetes, sickle-cell anemia, **amyloidosis**, **systemic lupus erythematosus**, **sarcoidosis**,

A specimen of a nephrotic human kidney. *(Custom Medical Stock Photo, Inc.)*

leukemia, lymphoma, cancer of the breast, colon, and stomach, reactions to drugs (including **nonsteroidal anti-inflammatory drugs**, lithium, and street heroine), allergic reactions (to insect stings, snake venom, and **poison ivy**), infections (**malaria**, various bacteria, **hepatitis B**, herpes zoster, and the virus which causes **AIDS**), and severe high blood pressure.

The first symptom of nephrotic syndrome is often foamy urine. As the syndrome progresses, swelling (**edema**) is noticed in the eyelids, hands, feet, knees, scrotum, and abdomen. The patient feels increasingly weak and fatigued. Appetite is greatly decreased. Over time, the loss of protein causes the muscles to become weak and small (called muscle wasting). The patient may note abdominal **pain** and difficulty breathing. Because the kidneys are involved in blood pressure regulation, abnormally low or abnormally high blood pressure may develop.

As the syndrome progresses the protein loss occurring in nephrotic syndrome will result in a generally malnourished state. Hair and nails become brittle, and growth is stunted. Bone becomes weak, and the body begins to lose other important nutrients (sugar, potassium, **calcium**). Infection is a serious and frequent complication, as are disorders of blood clotting. **Acute kidney failure** may develop.

KEY TERMS

Glomeruli—Tiny tufts of capillaries that carry blood within the kidneys. The blood is filtered by the glomeruli. The blood then continues through the circulatory system, but a certain amount of fluid and specific waste products are filtered out of the blood, to be removed from the body in the form of urine.

Immune system—The complex system within the body that serves to fight off harmful invaders, such as bacteria, viruses, fungi.

Kidney failure—The inability of the kidney to excrete toxic substances from the body.

Diagnosis

Tests

Diagnosis is based first on the laboratory examination of the urine and the blood. While the urine will reveal significant quantities of protein, the blood will reveal abnormally low amounts of circulating proteins. Blood tests also reveal a high level of **cholesterol**.

Procedures

In order to diagnose one of the kidney disorders that cause nephrotic syndrome, a small sample of the kidney will be removed for examination. This biopsy can be done with a long, very thin needle that is inserted through the skin under the ribs.

Treatment

Treatment depends on the underlying disorder that caused nephrotic syndrome.

Drugs

Medications that dampen the immune system are a mainstay of treatment. The first choice is usually a steroid drug (such as prednisone). Some conditions may require more potent medications, such as cyclophosphamide or cyclosporine. Treating the underlying conditions (lymphoma, cancers, heroine use, infections)

WWW.BOOKBAZ.IR

that have led to nephrotic syndrome often improve the symptoms of nephrotic syndrome as well. Some patients require the use of specific medications to control high blood pressure. Occasionally, the quantity of fluid a patient is allowed to drink is restricted. Some patients benefit from the use of **diuretics** (which allow the kidney to produce more urine) to decrease swelling.

Prognosis

Prognosis depends on the underlying disorder. Minimal change disease has the best prognosis of all the kidney disorders, with 90% of all patients responding to treatment. Other types of kidney diseases have less favorable outcomes, with high rates of progression to kidney failure. When nephrotic syndrome is caused by another, treatable disorder (infection, allergic or drug reaction), the prognosis is very good.

Nephrotoxic injury

Definition

Nephrotoxic injury is damage to one or both of the kidneys that results from exposure to a toxic material, usually through ingestion.

Description

The kidneys are the primary organs of the urinary system, which purifies the blood by removing wastes from it and excreting them from the body in urine. Every day, the kidneys filter about 45 gal (180 l) of blood, about four times as much as the amount that passes through any other organ. Because of this high volume, the kidneys are more often exposed to toxic substances in the blood and are very vulnerable to injury from those sources.

Each kidney contains more than one million structures called nephrons. Each nephron consists of two parts: the renal corpuscle and the renal tubule. The renal corpuscle is where the blood is filtered. It is made up of a network of capillaries (the glomerulus) and the structure that surrounds these capillaries (Bowman's capsule). Blood flows into the glomerulus, where the liquid part of the blood (plasma) passes through the walls of the capillaries and into Bowman's capsule (blood cells and some proteins are too big to pass through and therefore remain in the blood vessels). The plasma, now called filtrate, contains substances that the body needs, such as water, glucose, and other nutrients, as well as wastes, excess salts, and excess water. When the filtrate moves from Bowman's capsule into the renal tubules, about 99% of it is taken back up as the action of the tubules allows beneficial substances to be reabsorbed into the bloodstream. The remaining filtrate is then passed to the bladder as urine.

When the kidneys are exposed to a toxic agent, either accidentally or intentionally (as in a **suicide** attempt), damage can occur in a number of different ways, depending upon the agent. One toxin may directly affect the glomerulus or the renal tubules, causing the cells of these structures to die. Another toxin may create other substances or conditions that result in the same cell death. Nephrotoxic injury can lead to acute renal failure, in which the kidneys suddenly lose their ability to function, or chronic renal failure, in which kidney function slowly deteriorates. If unchecked, renal failure can result in death.

Causes and symptoms

Several different substances can be toxic to the kidneys. These include:

- antibiotics, primarily aminoglycosides, sulphonamides, amphotericin B, polymyxin, neomycin, bacitracin, rifampin, trimethoprim, cephaloridine, methicillin, aminosalicylic acid, and oxy- and chlorotetracyclines
- analgesics, including acetaminophen (Tylenol), all nonsteroidal anti-inflammatory drugs, or NSAIDs (e.g., aspirin, ibuprofen), and all prostaglandin synthetase inhibitors
- contrast agents used in some diagnostic tests, such as sodium iodide
- heavy metals, such as lead, mercury, arsenic, and uranium
- anti-cancer drugs, such as cyclosporin, cisplatin, and cyclophosphamide
- methemoglobin-producing agents
- solvents and fuels, such as carbon tetrachloride, methanol, amyl alcohol, and ethylene glycol
- herbicides and pesticides
- overproduction of uric acid

Nephrotoxic injury is most commonly caused by drugs, primarily **antibiotics**, **analgesics**, and contrast agents. In some cases, such as with **aminoglycosides** and amphotericin B, the drug itself will damage the kidneys. In others, such as with methicillin, sulphonamides, and some contrast agents, the drug provokes an allergic reaction that destroys the kidneys. Some chemicals found in certain drugs and industrial agents damage the kidneys by converting the hemoglobin of red blood cells into methemoglobin, thereby interfering with the blood's transport of oxygen. In hospitals, the most common form of nephrotoxic injury is antibiotic nephropathy, which usually occurs when antibiotics are given to patients with already weakened kidneys. Analgesic nephropathy is another common form of nephrotoxic injury and occurs as a result of long-term abuse of analgesics, usually NSAIDs (e.g., ibuprofen). Analgesic nephropathy is most prevalent in women over 30. Lead nephropathy, arising from **lead poisoning**, and nephropathy, from ingestion of the solvent carbon tetrachloride, are also more common forms of nephrotoxic injury. Uric acid nephropathy is one form of nephropathy that is not caused by exposure to an external toxin; instead, it arises from the body's overproduction of uric acid, usually in persons with diseases of the lymph nodes or bone marrow.

Risk factors for nephrotoxic injury include:

- Age. The elderly are more likely to overdose on antibiotics or analgesics.
- Underlying kidney disease. Kidneys already weakened by conditions such as diabetes can be particularly susceptible to nephrotoxic injury.
- Severe dehydration.
- Prolonged exposure to heavy metals or solvents on the job or in the home.
- Presence of diseases that cause the overproduction of uric acid.

KEY TERMS

Bowman's capsule—The structure surrounding the glomerulus.

Chelate—A chemical that binds to heavy metals in the blood, thereby helping the body to excrete them in urine.

Contrast agent—Substance ingested so as to highlight anatomical structures in x-ray imaging tests.

Diuretic—A drug that promotes the excretion of urine.

Glomerulus—A network of capillaries located in the nephron where wastes are filtered from the blood.

Methemoglobin—A compound formed from hemoglobin by oxidation.

Nephron—Basic functional unit of the kidney.

Nephrotoxin—Substance that is poisonous to the kidneys.

Renal failure—Disorder characterized by the kidney's inability to filter wastes from the blood. It may be acute (occuring suddenly and usually reversable) or chronic (developing slowly over time as a result of permanent damage).

Symptoms of nephrotoxic injury are wide ranging and, in some cases, depend upon the type of toxin involved. In general, symptoms are similar to those of renal failure and include excess urea in the blood (azotemia), anemia, increased hydrogen ion concentration in the blood (acidosis), excess fluids in the body (**overhydration**), and high blood pressure (**hypertension**). Blood or pus may be present in the urine, as may uric acid crystals. A decrease in urinary output may also occur. If the toxin's effect on the kidneys remains unchecked, more serious symptoms of kidney failure may occur, including seizures and **coma**.

Diagnosis

Damage to the kidneys is assessed through a combination of **physical examination**, blood tests, urine tests, and imaging procedures. Diagnosis of nephrotoxic injury

WWW.BOOKBAZ.IR

as the underlying cause results from a thorough investigation of the patient's history. Information regarding preexisting conditions, current prescriptions, and environmental exposures to toxins aid the physician in determining what toxin, if any, has caused the kidneys to malfunction.

Treatment

Treatment of nephrotoxic injury takes place in the hospital and focuses on removing the toxin from the patient's system, while maintaining kidney function. Removal methods are targeted to specific toxins and may include the use of **diuretics** or chelates to enhance excretion of the toxin in urine, or, in extreme cases, the direct removal of toxins from the blood via hemodialysis or passing the blood over an absorbent substance such as charcoal. Support of kidney function depends on the extent of damage to the organs and ranges from monitoring fluid levels to dialysis.

Prognosis

The outcome of nephrotoxic injury is determined by the cause and severity of the damage. In cases where damage has not progressed beyond acute renal failure, kidney function can be fully restored once the toxin is removed from the system and equilibrium restored. However, if permanent damage has resulted in chronic renal failure, lifelong dialysis or a kidney transplant may be required.

Prevention

Exposure to nephrotoxins can be minimized several different ways. When taking antibiotics or analgesics, recommended dosages should be strictly followed. Also, elderly patients on these medications (for example, those taking **aspirin** for heart problems or NSAIDs for arthritis) should be closely monitored to prevent accidental overdose. Healthcare workers should be aware of any underlying conditions, such as diabetes or **allergies** to antibiotics, that may heighten the effect of a potential nephrotoxin. When using solvents or handling heavy metals, procedures regarding their safe use should be employed.

Neuralgia

Definition

Neuralgia is defined as an intense burning or stabbing **pain** caused by irritation of or damage to a nerve. The pain is usually brief but may be severe. It often feels as if it is shooting along the course of the affected nerve.

Description

Different types of neuralgia occur depending on the reason the nerve has been irritated. Neuralgia can be triggered by a variety of causes, including **tooth decay**, eye strain, or **shingles** (an infection caused by the herpes zoster virus). Pain is usually felt in the part of the body that is supplied by the irritated nerve.

Demographics

Statistics on neuralgia vary according to the type and population surveyed. Regarding **trigeminal neuralgia**, an estimated one individual in 15,000 is afflicted, although numbers may be significantly higher due to frequent misdiagnosis. Neuralgia usually develops after the age of 40, although there have been cases with patients being as young as three years of age.

Causes and symptoms

Neuralgia is caused by irritation or nerve damage from systemic disease, inflammation, infection, and compression or physical irritation of a nerve. The location of the pain depends on the underlying condition that is irritating the nerve or the location of the particular nerve that is being irritated.

Neuralgia can result from tooth decay, poor diet, eye strain, nose infections, or exposure to damp and cold. Postherpetic neuralgia is an intense debilitating pain felt at the site of a previous attack of shingles. Trigeminal neuralgia (also called tic douloureux, the most common type of neuralgia), causes a brief, searing pain along the trigeminal nerve, which supplies sensation to the face. The facial pain of migraine neuralgia lasts between 30 minutes and an hour and occurs at the same time on successive days. The cause is not known.

Glossopharyngeal neuralgia is an intense pain felt at the back of the tongue, in the throat, and in the ear—all areas served by the glossopharyngeal nerve. The pain can occur spontaneously, or it can be triggered by talking, eating, or swallowing (especially cold foods such as ice cream). Its cause is not known.

Occipital neuralgia is caused by a pinched occipital nerve. There are two occipital nerves, each located at the back of the neck, each supplying feeling to the skin over half of the back of the head. These nerves can be pinched due to factors ranging from arthritis to injury, but the result is the same: numbness, pain, or tingling over half the base of the skull.

Diagnosis

Neuralgia is a symptom of an underlying disorder; its diagnosis depends on finding the cause of the condition creating the pain.

To diagnose occipital neuralgia, a doctor can inject a small amount of anesthetic into the region of the occipital nerve. If the pain temporarily disappears, and there are no other physical reasons for the pain, the doctor may recommend surgery to deal with the pinched nerve.

Treatment

Glossopharyngeal, trigeminal, and postherpetic neuralgias sometimes respond to **anticonvulsant drugs**, such as carbamazepine or phenytoin, or to painkillers, such as **acetaminophen**. Trigeminal neuralgia may also be relieved by surgery in which the nerve is cut or decompressed. In some cases, compression neuralgia (including occipital neuralgia) can be relieved by surgery.

People with shingles should see a doctor within three days of developing the rash, since aggressive treatment of the blisters that appear with the rash can ease the severity of the infection and minimize the risk of developing postherpetic neuralgia. However, it is not clear whether the treatment can prevent postherpetic neuralgia.

If postherpetic neuralgia develops, a variety of treatments can be tried, since their effectiveness varies from person to person.

- antidepressants such as amitriptyline (Elavil)
- anticonvulsants (phenytoin, valproate, or carbamazepine)
- capsaicin (Xostrix), the only medication approved by the FDA for treatment of postherpetic neuralgia
- topical painkillers
- desensitization
- TENS (transcutaneous electrical nerve stimulation)
- dorsal root zone (DREZ) surgery (a treatment of last resort)

Alternatives

B-complex **vitamins**, primarily given by intramuscular injection, can be an effective treatment. A whole-foods diet with adequate protein, carbohydrates, and

KEY TERMS

Desensitization—A technique of pain reduction in which the painful area is stimulated with whatever is causing the pain.

Dorsal root entry zone (DREZ)—A type of nerve surgery for postherpetic neuralgia that is occasionally used when the patient can get no other pain relief. The surgery destroys the area where damaged nerves join the central nervous system, thereby interfering with inappropriate pain messages from nerves to the brain.

Glossopharyngeal neuralgia—Sharp recurrent pain deep in the throat that extends to the area around the tonsils and possibly the ear. It is triggered by swallowing or chewing.

Migraine neuralgia—A variant of migraine pain, also called cluster headache, in which severe attacks of pain affect the eye and forehead on one side of the face.

Occipital neuralgia—Pain on one side of the back of the head caused by entrapment or pinching of an occipital nerve.

Postherpetic neuralgia—Persistent pain that occurs as a complication of a herpes zoster infection. Although the pain can be treated, the response is variable.

Shingles—A painful rash with blisters that appears along the course of a nerve. It is caused by infection with herpes zoster virus.

TENS—The abbreviation for transcutaneous electrical nerve stimulation, a technique used to control chronic pain. Electrodes placed over the painful area deliver a mild electrical impulse to nearby nerve pathways, thereby easing pain.

Trigeminal neuralgia—Brief episodes of severe shooting pain on one side of the face caused by inflammation of the root of the trigeminal nerve. Also referred to as tic douloureux.

WWW.BOOKBAZ.IR

fats that also includes yeast, liver, wheat germ, and foods that are high in B vitamins may be helpful. **Acupuncture** is a very effective treatment, especially for postherpetic neuralgia. Homeopathic treatment can also be effective when the correct remedy is used. Some botanical medicines may also be useful. For example, black cohosh (*Cimicifuga racemosa*) appears to have anti-inflammatory properties based on some research.

Prognosis

The effectiveness of the treatment depends on the cause of the neuralgia, but many cases respond to pain relief.

Trigeminal neuralgia tends to come and go, but successive attacks may be disabling. Although neuralgia is not fatal, the patient's fear of being in pain can seriously interfere with daily life.

Some people with postherpetic neuralgia respond completely to treatment. Most people, however, experience some pain after treatment, and a few receive no relief at all. Some people live with this type of neuralgia for the rest of their lives, but for most, the condition gradually fades within five years.

Carol A. Turkington

Neuroblastoma

Definition

Neuroblastoma is a type of cancer that usually originates either in the tissues of the adrenal gland or in the ganglia of the abdomen or in the ganglia of the nervous system. (Ganglia are masses of nerve tissue or groups of nerve cells.) Tumors develop in the nerve tissue in the neck, chest, abdomen, or pelvis.

Description

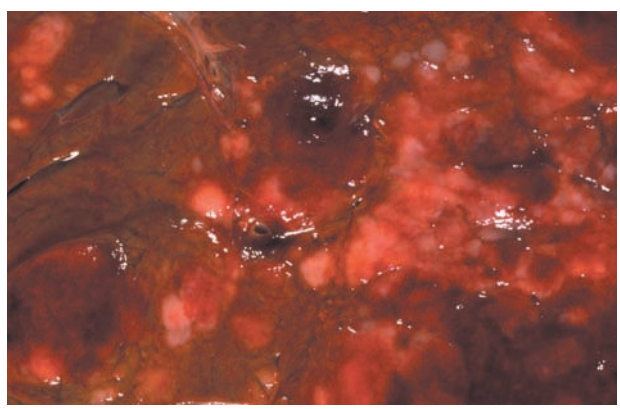
Neuroblastoma is one of the few cancer types known to secrete hormones. It occurs most often in children, and it is the third most common cancer that occurs in children. Approximately 7.5% of the childhood cancers diagnosed in 2001 were neuroblastomas, affecting one in 80,000 to 100,000 children in the United States. Close to 50% of cases of neuroblastoma occur in children younger than two years old. The disease is sometimes present at birth, but is usually not noticed until later. By the time the disease is diagnosed, it has often spread to the lymph nodes, liver, lungs, bones, or bone marrow. Approximately one-third of neuroblastomas start in the adrenal glands.

Demographics

According to some reports, African-American children develop the disease at a slightly higher rate than Caucasian children (8.7 per million compared to 8.0 per million cases diagnosed).

Causes and symptoms

The causes of neuroblastoma are not precisely known. Current research holds that neuroblastomas



A neuroblastoma appearing at the surface of the liver. *(Custom Medical Stock Photo, Inc.)*

develop when cells produced by the fetus (neuroblast cells) fail to mature into normal nerve or adrenal cells and keep growing and proliferating. The first symptom of a neuroblastoma is usually an unusual growth or lump, found in most cases in the abdomen of the child, causing discomfort or a sensation of fullness and **pain**. Other symptoms such as numbness and **fatigue**, arise because of pressure caused by the tumor. Bone pain also occurs if the cancer has spread to the bone. If it has spread to the area behind the eye, the cancer may cause protruding eyes and dark circles around the eyes; in a few cases, blindness may be the presenting symptom. **Paralysis** may result from compression of the spinal cord. **Fever** is also reported in one case out of four. High blood pressure, persistent **diarrhea**, rapid heartbeat, reddening of the skin, and sweating occur occasionally. Some children may also have uncoordinated or jerky muscle movements, or uncontrollable eye movements, but these symptoms are rare. If the disease spreads to the skin, blue or purple patches may appear.

Diagnosis

A diagnosis of neuroblastoma usually requires blood and urine tests to investigate the nature and quantity of chemicals (neurotransmitters) released by the nerve cells. These are broken down by the body and released in urine. Additionally, scanning techniques are used to confirm the diagnosis of neuroblastoma. These techniques produce images or pictures of the inside of the body and they include computed tomography scan (CT scan) and **magnetic resonance imaging** (MRI). To confirm the diagnosis, the physician will surgically remove some of the tissue from the tumor or bone marrow, and examine the cells under the microscope (biopsy).

Treatment

The treatment team usually consists of an oncologist specialized in the treatment of neuroblastoma, a surgeon to perform biopsies and possibly attempt surgical removal of the tumor, a **radiation therapy** team and, if indicated, a **bone marrow transplantation** team.

Staging

Once neuroblastoma has been diagnosed, the physician will perform more tests to determine if the cancer has spread to other tissues in the body. This process, called staging, is important for the physician to determine how to treat the cancer and check liver and kidney function. The staging system for neuroblastoma is based on how far the disease has spread from its original site to other tissues in the body.

Localized resectable (able to be cut out) neuroblastoma is confined to the site of origin, with no evidence that it has spread to other tissues, and the cancer can be surgically removed. Localized unresectable neuroblastoma is confined to the site of origin, but the cancer cannot be completely removed surgically. Regional neuroblastoma has extended beyond its original site to regional lymph nodes, and/or surrounding organs or tissues, but has not spread to distant sites in the body. Disseminated neuroblastoma has spread to distant lymph nodes, bone, liver, skin, bone marrow, and/or other organs. Stage 4S (or IVS, or "special") neuroblastoma has spread only to liver, skin, and/or, to a very limited extent, bone marrow. Recurrent neuroblastoma means that the cancer has come back, or continued to spread after it has been treated. It may come back in the original site or in another part of the body.

Treatments are available for children with all stages of neuroblastoma. More than one of these treatments may be used, depending on the stage of the disease. The four types of treatment used are:

- surgery (removing the tumor in an operation)
- radiation therapy (using high-energy x rays to kill cancer cells)
- chemotherapy (using drugs to kill cancer cells)
- bone marrow transplantation (replacing the patient's bone marrow cells with those from a healthy person)

Surgery is used whenever possible, to remove as much of the cancer as possible, and can generally cure the disease if the cancer has not spread to other areas of the body. Before surgery, **chemotherapy** may be used to shrink the tumor so that it can be more easily removed during surgery; this is called neoadjuvant chemotherapy. Radiation therapy is often used after surgery; high-energy rays (radiation) are used to kill as many of the remaining cancer cells as possible. Chemotherapy (called adjuvant chemotherapy) may also be used after surgery to kill remaining cells. Bone marrow transplantation is used to replace bone marrow cells killed by radiation or chemotherapy. In some cases the patient's own bone marrow is removed prior to treatment and saved for transplantation later. Other times the bone marrow comes from a "matched" donor, such as a sibling.

One novel approach to treatment of neuroblastomas is therapy with desferoxamine (DFO), which is ordinarily used to treat iron **poisoning**. DFO has been shown to have antitumor activity in neuroblastomas and other cancers of the central nervous system. It is

WWW.BOOKBAZ.IR

KEY TERMS

Adjuvant chemotherapy—Treatment of the tumor with drugs after surgery to kill as many of the remaining cancer cells as possible.

Adrenal gland—Gland located above each kidney consisting of an outer wall (cortex) that produces steroid hormones and an inner section (medulla) that produces other important hormones, such as adrenaline and noradrenaline.

Alternative therapy—A therapy is generally called alternative when it is used instead of conventional cancer treatments.

Biopsy—A small sample of tissue removed from the site of the tumor to be examined under a microscope.

Conventional therapy—Treatments that are widely accepted and practiced by the mainstream medical community.

Complementary therapy—A therapy is called complementary when it is used in addition to conventional cancer treatments.

Disseminated—Spread to other tissues.

Hormone—A substance produced by specialized cells that affects the way the body carries out the biochemical and energy-producing processes required to maintain health (metabolism.

Localized—Confined to a small area.

Neoadjuvant chemotherapy—Treatment of the tumor with drugs before surgery to reduce the size of the tumor.

Neuroblast cells—Cells produced by the fetus which mature into nerve cells and adrenal medulla cells.

Monoclonal antibody—A protein substance which is produced in the laboratory by a single population of cells. They are being tested as a possible form of cancer treatment.

Resectable cancer—A tumor that can be surgically removed.

Salvage therapy—Treatment measures taken late in the course of a disease after other therapies have failed. It is also known as rescue therapy.

Staging system—A system based on how far the cancer has spread from its original site, developed to help the physician determine how best to treat the disease.

Unresectable cancer—A tumor that cannot be completely removed by surgery.

thought that the drug works by lowering the increased iron levels in the body associated with cancer.

There are significant differences in treatment protocols for neuroblastoma between the major North American study group (Children's Oncology Group) and its European counterpart, the Société Internationale d'Oncologie Pédiatrique (SIOP). These differences include biopsy techniques, the timing and extent of surgery, chemotherapy dosages, and the types of salvage therapy employed.

Alternatives

No alternative therapy has yet been reported as a substitute for conventional neuroblastoma treatment. Complementary therapies—such as retinoic acid therapy—have been shown to be beneficial to patients when administered after a conventional course of chemotherapy or transplantation.

Prognosis

The chances of recovery from neuroblastoma depend on the stage of the cancer, the age of the child at diagnosis, the location of the tumor, and the state and nature of the tumor cells evaluated under the microscope. Infants have a higher rate of cure than do children over one year of age, even when the disease has spread.

After completion of a course of treatment for neuroblastoma, physicians sometimes recommend that the child undergo an investigative operation. This procedure allows the treatment team to evaluate how effective treatment has been, and may offer an opportunity to remove more of the tumor if it is still present.

In general, the prognosis for a young child with neuroblastoma is good: the predicted five-year survival rate is approximately 85% for children who had the onset of the disease in infancy, and 35% for those whose disease developed later.

Prevention

Neuroblastoma may be a genetic disease passed down from the parents. In 2004, a group of German researchers reported that a series of neuroblastomas demonstrated a consistent pattern of deletions and overrepresentations on chromosomes 3, 10,

17q, and 20. There is currently no known method for its prevention.

Neuroendocrine tumors

Definition

Neuroendocrine tumor refers to the type of cell that a tumor grows from rather than where that tumor is located. Neuroendocrine cells produce hormones or regulatory proteins, and so tumors of these cells usually have symptoms that are related to the specific hormones that they produce.

Description

Neuroendocrine cells have roles both in the endocrine system and the nervous system. They produce and secrete a variety of regulatory hormones, or neuropeptides, which include neurotransmitters and growth factors. When these cells become cancerous, they grow and overproduce their specific neuropeptide. Neuroendocrine tumors are generally rare. One type of neuroendocrine tumor is a carcinoid tumor. This type of tumor can occur in the intestinal tract, appendix, rectum, bronchial tubes, or ovary. Most carcinoid tumors secrete serotonin. When the blood concentration of this hormone is high enough, it causes carcinoid syndrome. This syndrome refers to a variety of symptoms that are caused by the excessive amount of hormone secreted rather than the tumor itself.

The total incidence of neuroendocrine tumors is thought to be between five and nine million people in the United States. It is possible that these tumors are underreported because they grow slowly and do not always produce dramatic symptoms.

Causes and symptoms

Many of the symptoms of carcinoid tumor are due to the hormones that the tumor secretes. These hormones can affect the whole body and cause what is referred to as carcinoid syndrome. The most common symptom of carcinoid syndrome is flushing, a sudden appearance of redness and warmth in the face and neck that can last from minutes to hours. Other symptoms of carcinoid syndrome are **diarrhea**, asthma-like symptoms and heart problems. Since most carcinoid tumors are found in the appendix, the symptoms are often similar to **appendicitis**, primarily **pain** in the abdomen. When these tumors are found in the small intestine, they can cause abdominal pain that is often initially diagnosed as bowel obstruction. Many patients have no symptoms and the carcinoids are found during routine **endoscopy** of the intestines.

Diagnosis

The diagnosis of carcinoid syndrome is made by the measurement of 5–hydroxy indole acetic acid (5–HIAA) in the urine. 5–HIAA is a breakdown (waste) product of serotonin. If the syndrome is diagnosed, the presence of carcinoid tumor is a given. When the syndrome is not present, diagnosis may be delayed, due to the vague symptoms present. Diagnosis can sometimes take up to two years. It is made by performing a number of tests, and the specific test used depends on the tumor's suspected location. The tests that may be performed include gastrointestinal endoscopy,

WWW.BOOKBAZ.IR

KEY TERMS

Appendicitis—Inflammation of the appendix.

Growth factor—A local hormone produced by some cells that initiates growth.

Metastasis—The spread of disease from one part of the body to another, as when cancer cells appear in parts of the body remote from the site of the primary tumor.

Neurotransmitter—A chemical messenger used to transmit information in the nervous system.

chest x ray, computed tomography scan (CT scan), **magnetic resonance imaging**, or **ultrasound**. A biopsy of the tumor is performed for diagnosis. A variety of hormones can be measured in the blood as well to indicate the presence of a carcinoid.

Treatment

The only effective treatment for carcinoid tumor is surgical removal of the tumor. Although **chemotherapy** is sometimes used when metastasis has occurred, it is rarely effective. The treatment for carcinoid syndrome is typically meant to decrease the severity of symptoms. Patients should avoid **stress** as well as foods that bring on the syndrome. Some medications can be given for symptomatic relief; for example, tumors of the gastrointestinal tract may be treated with octreotide (Sandostatin) or lanreotide (Somatuline) to relieve such symptoms as diarrhea and flushing. These drugs are known as somatostatin analogs.

Liver transplantation is a treatment option for patients with neuroendocrine tumors that have metastasized only to the liver. This approach is reported to offer patients long, disease-free periods and relief of symptoms.

Prognosis

The prognosis of carcinoid tumors is related to the specific growth patterns of that tumor, as well as its location. For example, a group of researchers at the University of Wisconsin reported in 2004 that patients with gastrointestinal tumors in the hindgut had longer periods of disease-free survival than those with foregut or midgut cancers. For localized disease the five-year survival rate can be 94%, whereas for patients where metastasis has occurred, the average five-year survival rate is 18%. It is not unusual for patients with carcinoid tumors to live 10–15 years after the initial diagnosis.

Prevention

Neuroendocrine tumors such as carcinoid tumors are rare, and no information consequently is yet available on cause or prevention.

Neurofibromatosis

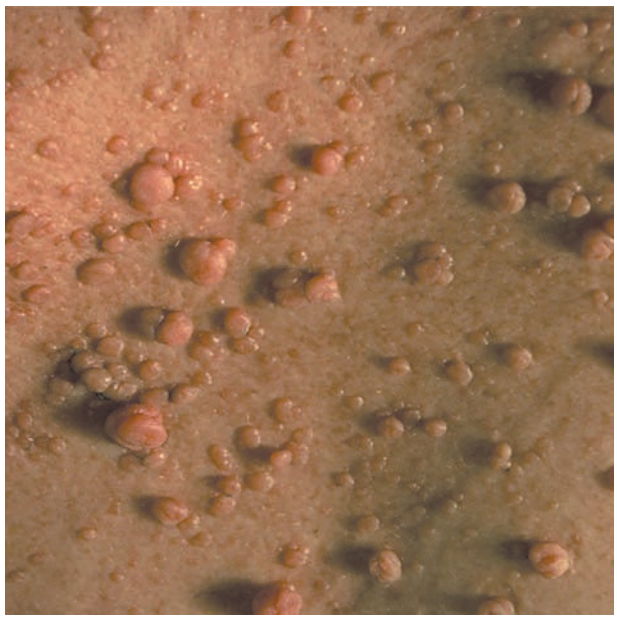
Definition

Neurofibromatosis (NF), or von Recklinghausen disease, is a genetic disease in which patients develop multiple soft tumors (neurofibromas). These tumors occur under the skin and throughout the nervous system.

Description

Neural crest cells are primitive cells which exist during fetal development. These cells eventually turn into:

- cells which form nerves throughout the brain, spinal cord, and body
- cells which serve as coverings around the nerves that course through the body
- pigment cells, which provide color to structures



This person's skin has multiple soft tumors, or neurofibromas. Such tumors develop underneath the skin. *(Custom Medical Stock Photo, Inc.)*

- the meninges, the thin, membranous coverings of the brain and spinal cord
- cells which ultimately develop into the bony structures of the head and neck

In neurofibromatosis, a genetic defect causes these neural crest cells to develop abnormally. This results in numerous tumors and malformations of the nerves, bones, and skin.

Neurofibromatosis occurs in about one of every 4,000 births. Two types of NF exist: NF-1 (90% of all cases) and NF-2 (10% of all cases).

Causes and symptoms

Both forms of neurofibromatosis are caused by a defective gene. NF-1 is due to a defect on chromosome 17; NF-2 results from a defect on chromosome 22. Both of these disorders are inherited in a dominant fashion. This means that anybody who receives just one defective gene will have the disease. However, a family pattern of NF is only evident in about half of all cases of NF. The other cases of NF occur due to a spontaneous mutation (a permanent change in the structure of a specific gene). Once such a spontaneous mutation has been established in an individual, however, it is then possible to be passed on to any offspring. The chance of a person with NF passing on the NF gene to a child is 50%.

NF-1 has a number of possible signs and can be diagnosed if any two of the following are present:

- The presence of café-au-lait (French for coffee-with-milk) spots. These are patches of tan or light brown skin, usually about 5-15 mm in diameter. Nearly all patients with NF-1 will display these spots.
- Multiple freckles in the armpit or groin area.
- Ninty percent of patients with NF-1 have tiny tumors called Lisch nodules in the iris (colored area) of the eye.
- Neurofibromas. These soft tumors are the hallmark of NF-1. They occur under the skin, often located along nerves or within the gastrointestinal tract. Neurofibromas are small and rubbery, and the skin overlying them may be somewhat purple in color.
- Skeletal deformities, such as a twisted spine (scoliosis), curved spine (humpback), or bowed legs.
- Tumors along the optic nerve, which cause vision disturbance in about 20% of patients.
- The presence of NF-1 in a patient's parent, child, or sibling.

There are very high rates of speech impairment, learning disabilities, and attention deficit disorder in children with NF-1. Other complications include the development of a **seizure disorder**, or the abnormal accumulation of fluid within the brain (**hydrocephalus**). A number of cancers are more common in patients with NF-1. These include a variety of types of malignant brain tumors, as well as leukemia, and cancerous tumors of certain muscles (rhabdomyosarcoma), the adrenal glands (**pheochromocytoma**), or the kidneys (Wilms' tumor).

Patients with NF-2 do not necessarily have the same characteristic skin symptoms (café-au-lait spots, freckling, and neurofibromas of the skin) that appear in NF-1. The characteristic symptoms of NF-2 are due to tumors along the acoustic nerve. Interfering with the function of this nerve results in the loss of hearing; and the tumor may spread to neighboring nervous system structures, causing weakness of the muscles of the face, **headache**, **dizziness**, poor balance, and uncoordinated walking. Cloudy areas on the lens of the eye (called **cataracts**) frequently develop at an unusually early age. As in NF-1, the chance of brain tumors developing is unusually high.

Diagnosis

Diagnosis is based on the symptoms outlined above. Diagnosis of NF-1 requires that at least two of the listed signs are present. Diagnosis of NF-2 requires the presence of either a mass on the acoustic

WWW.BOOKBAZ.IR

KEY TERMS

Chromosome—A structure within the nucleus of every cell, which contains genetic information governing the organism's development.

Mutation—A permanent change to the genetic code of an organism. Once established, a mutation can be passed on to offspring.

Neurofibroma—A soft tumor usually located on a nerve.

Tumor—An abnormal multiplying mass of cells.

nerve or another distinctive nervous system tumor. An important diagnostic clue for either NF-1 or NF-2 is the presence of the disorder in a patient's parent, child, or sibling.

Monitoring the progression of neurofibromatosis involves careful testing of vision and hearing. X-ray studies of the bones are frequently done to watch for the development of deformities. CT scans and MRI scans are performed to track the development/progression of tumors in the brain and along the nerves. Auditory evoked potentials (the electric response evoked in the cerebral cortex by stimulation of the acoustic nerve) may be helpful to determine involvement of the acoustic nerve, and EEG (electroencephalogram, a record of electrical currents in the brain) may be needed for patients with suspected seizures.

Treatment

There are no available treatments for the disorders that underlie either type of neurofibromatosis. To some extent, the symptoms of NF-1 and NF-2 can be treated individually. Skin tumors can be surgically removed. Some brain tumors, and tumors along the nerves, can be surgically removed, or treated with drugs (**chemotherapy**) or x-ray treatments (**radiation therapy**). Twisting or curving of the spine and bowed legs may require surgical treatment, or the wearing of a special brace.

Prognosis

Prognosis varies depending on the types of tumors which an individual develops. As tumors grow, they begin to destroy surrounding nerves and structures. Ultimately, this destruction can result in blindness, deafness, increasingly poor balance, and increasing difficulty with the coordination necessary for walking. Deformities of the bones and spine can also interfere with walking and movement. When cancers develop, prognosis worsens according to the specific type of cancer.

Prevention

There is no known way to prevent the approximately 50% of all NF cases that occur due to a spontaneous change in the genes (mutation). New cases of inherited NF can be prevented with careful **genetic counseling** so that a person with NF understands that each of his or her offspring has a 50% chance of also having NF. When a parent has NF, and the specific genetic defect causing the parent's disease has been identified, tests can be performed on the fetus so that a during **pregnancy**. **Amniocentesis** or **chorionic villus sampling** are two techniques which allow small amounts of the developing baby's cells to be removed for examination. The tissue can then be examined for the presence of the parent's genetic defect. Some families choose to use this information in order to prepare for the arrival of a child with a serious medical problem. Other families may choose not to continue the pregnancy.

Neurogenic bladder

Definition

Neurogenic bladder is a dysfunction that results from interference with the normal nerve pathways associated with urination.

Description

Normal bladder function is dependent on the nerves that sense the fullness of the bladder (sensory nerves) and on those that trigger the muscle movements

that either empty it or retain urine (motor nerves). The reflex to urinate is triggered when the bladder fills to 300–500 mL. The bladder is then emptied when the contraction of the bladder wall muscles forces urine out through the urethra. The bladder, internal sphincters, and external sphincters may all be affected by nerve disorders that create abnormalities in bladder function.

There are two categories of neurogenic bladder dysfunction: overactive (spastic or hyper-reflexive) and underactive (flaccid or hypotonic). An overactive neurogenic bladder is characterized by uncontrolled, frequent expulsion of urine from the bladder. There is reduced bladder capacity and incomplete emptying of urine. An underactive neurogenic bladder has a capacity that is extremely large (up to 2000 mL). Due to a loss of the sensation of bladder filling, the bladder does not contract forcefully, and small amounts of urine dribble from the urethra as the bladder pressure reaches a breakthrough point.

Causes and symptoms

There are numerous causes for neurogenic bladder dysfunction and symptoms vary depending on the cause. An **overactive bladder** is caused by interruptions in the nerve pathways to the bladder occurring above the sacrum (five fused spinal vertebrae located just above the tailbone, or coccyx). This nerve damage results in a loss of sensation and motor control and is often seen in **stroke**, Parkinson's disease, and most forms of spinal-cord injuries. An underactive bladder is the result of interrupted bladder stimulation at the level of the sacral nerves. This may result from certain types of surgery on the spinal cord, sacral spinal tumors, or congenital defects. It also may be a complication of various diseases, such as **syphilis**, **diabetes mellitus**, or **polio**.

Diagnosis

Neurogenic bladder is diagnosed by carefully recording fluid intake and urinary output and by measuring the quantity of urine remaining in the bladder after voiding (residual urine volume). This measurement is done by draining the bladder with a small rubber tube (catheter) after the person has urinated. Kidney function also is evaluated by regular laboratory testing of the blood and urine. **Cystometry** may be used to estimate the capacity of the bladder and the pressure changes within it. These measurements can help determine changes in bladder compliance in order to assess the effectiveness of treatment. Doctors may use a cystoscope to look inside the bladder and tubes that lead to it from the kidneys (ureters). **Cystoscopy** may be used to assess the loss of muscle fibers and elastic tissues and, in some cases, for removing small pieces of tissue for examination (biopsy).

Treatment

Doctors begin treating neurogenic bladder by attempting to reduce bladder stretching (distension) through intermittent or continuous catheterization. In intermittent catheterization, a small rubber catheter is inserted at regular intervals (four to six times per day) to approximate normal bladder function. This avoids the complications that may occur when a catheter remains in the bladder's outside opening (urethra) continuously (an indwelling catheter). Intermittent catheterization should be performed using strict sterile technique (asepsis) by skilled personnel, and hourly fluid intake and output must be recorded. Patients who can use their arms may be taught to catheterize themselves.

Indwelling catheters avoid distension by emptying the bladder continuously into a bedside drainage collector. Individuals with indwelling catheters are encouraged to maintain a high fluid intake in order to prevent bacteria from accumulating and growing in the urine. Increased fluid intake also decreases the concentration of **calcium** in the urine, minimizing urine crystallization and the subsequent formation of stones. Moving around as much as possible and a low calcium diet also help to reduce stone formation.

Drugs may be used to control the symptoms produced by a neurogenic bladder. The unwanted contractions of an overactive bladder with only small volumes of urine may be suppressed by drugs that relax the bladder (anticholinergics) such as propantheline (Pro-Banthine) and oxybutynin (Ditropan). Contraction of an underactive bladder with normal bladder volumes may be stimulated with parasympathomimetics (drugs that mimic the action resulting from stimulation of the parasympathetic nerves) such as bethanechol (Urecholine).

Long-term management for the individual with an overactive bladder is aimed at establishing an effective spontaneous reflex voiding. The amount of fluid taken in is controlled in measured amounts during the waking hours, with sips only toward bedtime to avoid bladder distension. At regular intervals during the day (every four to six hours when fluid intake is two to three liters per 24 hours), the patient attempts to void using pressure over the bladder (Crede maneuver). The patient may also stimulate reflex voiding by abdominal tapping or stretching of the anal sphincter.

WWW.BOOKBAZ.IR

KEY TERMS

Anticholinergic—An agent that blocks certain nerve impulses.

Catheterization—Insertion of a slender, flexible tube into the bladder to drain urine.

Compliance—A term used to describe how well a patient's behavior follows medical advice.

Cystometry—A test of bladder function in which pressure and volume of fluid in the bladder are measured during filling, storage, and voiding.

Cystoscopy—A direct method of bladder study and visualization using a cystoscope (self-contained optical lens system). The cystoscope can be manipulated to view the entire bladder, with a guide system to pass it up into the ureters (tubes leading from the kidneys to the bladder).

Glans penis—The bulbous tip of the penis.

Motor nerves—Nerves that cause movement when stimulated.

Parasympathomimetic—An agent whose effects mimic those resulting from stimulation of the parasympathetic nerves.

Perineal—The diamond-shaped region of the body between the pubic arch and the anus.

Reflex—An involuntary response to a particular stimulus.

Sensory nerves—Nerves that convey impulses from sense organs to the higher parts of the nervous system, including the brain.

Sphincter—A band of muscles that surrounds a natural opening in the body; these muscles can open or close the opening by relaxing or contracting.

Ureter—A tube leading from one of the kidneys to the bladder.

Urethra—The tube that leads from the bladder to the outside of the body.

Urostomy—A diversion of the urinary flow away from the bladder, resulting in output through the abdominal wall. The most common method involves use of a portion of intestine to conduct the urine out through the abdomen and into an external pouch worn for urine collection.

The **Valsalva maneuver**, involving efforts similar to those used when straining to pass stool, produces an increase in intra-abdominal pressure that is sometimes adequate to completely empty the bladder. The amount of urine remaining in the bladder (residual volume) is estimated by a comparison of fluid intake and output. The patient also may be catheterized immediately following the voiding attempt to determine residual urine. Catheterization intervals are lengthened as the residual urine volume decreases and catheterization may be discontinued when urine residuals are at an acceptable level to prevent **urinary tract infection**.

For an underactive bladder, the patient may be placed on a similar bladder routine with fluid intake and output adjusted to prevent bladder distension. If an adequate voiding reflex cannot be induced, the patient may be maintained on clean intermittent catheterization.

Some individuals who are unable to control urine output (**urinary incontinence**) due to deficient sphincter tone may benefit from perineal exercises. Although this is a somewhat dated technique, male patients with extensive sphincter damage may be helped by the use of a Cunningham clamp. The clamp is applied in a horizontal fashion behind the glans of the penis and must be removed approximately every four hours for bladder emptying to prevent bacteria from growing in the urine and causing an infection. Alternation of the Cunningham clamp with use of a condom collection device will reduce the skin irritation sometimes caused by the clamp.

Surgery is another treatment option for incontinence. Urinary diversion away from the bladder may involve creation of a urostomy or a continent diversion. The surgical implantation of an inflatable sphincter is another option for certain patients. An indwelling urinary catheter is sometimes used when all other methods of incontinence management have failed. The long-term use of an indwelling catheter almost inevitably leads to some urinary tract infections, and contributes to the formation of urinary stones (calculi). Doctors may prescribe **antibiotics** preventively to reduce recurrent urinary tract infection.

Alternatives

The cause of the bladder problem must be determined and treated appropriately. If nerve damage is not permanent, homeopathy and **acupuncture** may help restore function.

Prognosis

Individuals with an overactive bladder caused by spinal cord lesions at or above the seventh thoracic vertebra, are at risk for sympathetic dysreflexia, a life-threatening condition which can occur when the bladder (and/or rectum) becomes overly full. Initial symptoms include sweating (particularly on the forehead) and **headache**, with progression to slow heart rate (bradycardia) and high blood pressure (**hypertension**). Patients should notify their physician promptly if symptoms do not subside after the bladder (or rectum) is emptied, or if the bladder (or rectum) is full and cannot be emptied.

Neuroleptics *see* **Antipsychotic drugs**

Neurolinguistic programming

Definition

Neurolinguistic programming (NLP) is aimed at enhancing the healing process by changing the conscious and subconscious beliefs of patients about themselves, their illnesses, and the world. These limiting beliefs are "reprogrammed" using a variety of techniques drawn from other disciplines including **hypnotherapy** and **psychotherapy**.

Purpose

Neurolinguistic programming has been used to change the limiting beliefs of patients about their prospects of recovery from a wide variety of medical conditions including Parkinson's disease, **AIDS**, migraines, arthritis, and cancer. Practitioners claim to be able to cure most **phobias** in less than one hour, and to help in making lifestyle changes regarding **exercise**, diet, **smoking**, etc. NLP has also been used to treat **allergies**. In other fields, claimed benefits include improved relationships, communication, motivation, and business performance.

Description

Origins

NLP was originally developed during the early 1970s by linguistics professor John Grinder, and psychology and mathematics student Richard Bandler, both of the University of California at Santa Cruz.

Studying the well-known psychotherapist Virginia Satir, the hypnotherapist Milton Erickson, the anthropologist Gregory Bateson, and others whom they considered "charismatic superstars" in their fields, Grinder and Bandler identified psychological, linguistic, and behavioral characteristics that they said contributed to the greatness of these individuals. On the other hand, they found that persons experiencing emotional difficulties could be similarly identified by posture, breathing pattern, choice of words, voice tone, eye movements, body language, and other characteristics.

Grinder and Bandler then focused on using these indicators to analyze and alter patterns of thought and behavior. After publishing their findings in two books in 1975, Grinder and Bandler parted company with one another, with a number of other collaborators, and with the University of California, continuing their work on NLP outside the formal world of academia. As a result, NLP split into a number of competing schools.

Popularized by television "infomercial" personality Anthony Robbins and others, NLP was quickly adopted in management and self-improvement circles. During the 1990s, there was growing interest in NLP's healing potential.

In a healthcare context, practitioners of neurolinguistic programming first seek to identify the negative attitudes and beliefs with which a client has been "programmed" since birth. This is accomplished by asking questions and observing physical responses such as changes in skin color, muscle tension, etc. Then, a wide variety of techniques is employed to "reprogram" limiting beliefs. For example, clients with chronic illness such as AIDS or cancer might be asked to displace the despair and loss of identity caused by the disease by visualizing themselves in vigorous health. Treatment by NLP practitioners is often of shorter duration than that of other alternative practitioners, but NLP self-help seminars and courses can be quite expensive.

WWW.BOOKBAZ.IR

For those who wish to try self-treatment with NLP, a wide variety of books, audio tapes, and videos are available.

Precautions

NLP is particularly popular in the self-improvement and career-development fields, and some trainers and practitioners have little experience in its use for healing. Practitioners should be specifically asked about this.

Because NLP is intended to enhance the healing process, it should not be used independently of other healing methods. In all cases of serious illness, a physician should be consulted.

Side effects

NLP is believed to be generally free of harmful side effects.

Research and general acceptance

Although some physicians and mental health practitioners employ principles of neurolinguistic programming, the field is generally considered outside of mainstream medical practice and academic thinking.

Neurologic bladder dysfunction

see **Neurogenic bladder**

Neurological exam

Definition

A neurological exam—also called a neurologic or neuro exam—is an evaluation of the nervous system, including the brain, spinal cord, the 12 cranial nerves that come from the brain, and the nerves that come from the spinal cord. A neurological exam uses observation and simple tests to assess motor and sensory skills and mental status. Motor skills include reflexes, muscle strength, eye and mouth movement, and coordination, balance, and gait. Sensory skills include hearing and speech, vision, taste, and smell. Mental status includes alertness, awareness of and interaction with one's environment, and mood and behavioral changes.

Description

A neurological exam is neither invasive nor painful. It can be performed in a physician's office and involves only simple instruments such as a reflex hammer, tuning fork, needles, a light, and an ophthalmoscope. The simplest aspects of a neurological exam involve observing a patient's gait and coordination and whether the eyelids are drooping. However, some specialized exams may require a neurologist to perform the tests and analyze the results. The extent of a neurological exam depends on the symptoms being evaluated and the patient's age and medical condition. For some injuries it may be necessary to repeat portions of the exam after swelling from the injury has decreased. In some cases, such as after a **stroke**, neurological exams may be repeated at regular intervals to monitor the condition.

A neurological exam focuses on the following:

- motor skills, including reflexes, muscle strength, head and facial movements, coordination, balance, and gait
- sensory skills
- mental status and basic cognitive skills
- cranial nerves

Motor nerve function—especially deep tendon reflexes—are central to a neurological exam. Deep tendon reflexes, also known as muscle stretch reflexes, are tendon responses to stimuli. Normally, tapping specific areas of tendons with a soft rubber hammer causes the muscle fibers to contract. The physician taps various points with a reflex hammer and observes any decrease in responsiveness.

The Babinski reflex is an important component of motor system evaluation. In patients over the age of two, stroking or scratching the outer side of the sole of the foot in a heel-to-toe direction normally causes the toes to curl downward. A brain or **spinal cord injury** is indicated by the toes fanning upward.

The physician examine the patient's muscles for atrophy (shrinkage), twitching, or abnormal movements. Tests may be performed to evaluate the strength of all major muscle groups. Specific tests may include:

- squeezing fingers

JEAN-MARTIN CHARCOT (1825–1893)

Jean-Martin Charcot. *(Photo Researchers Inc)*

French physician, researcher, and teacher Jean-Martin Charcot is generally credited with establishing the foundation of modern neurology. Charcot was born in Paris to a working-class family. His father built coaches and could not afford to send all four of his sons to college. Charcot, the most promising of the children, was selected and decided to study medicine.

Charcot excelled at his studies from the beginning and rose quickly through the ranks. He enjoyed drawing and painting, and his talent became extremely useful as he created detailed drawings of human anatomy. After becoming certified as a physician, Charcot obtained a position at Salpêtriere Hospital. He remained at Salpêtriere for a large portion of his life, moving from junior physician to senior physician and eventually obtaining the post of director of the hospital.

During the mid-1800s, Salpêtriere had about 5,000 patients at any given time. The patient population was made up mainly of individuals identified as insane and women who were disabled or suffering from epilepsy, hysteria, or other neurological disorders. This population provided a fertile environment for Charcot to work on identifying the underlying pathologies associated with various neurological symptoms.

Charcot conducted research into a wide variety of ailments. He was the first to introduce geriatrics, the branch of medicine dealing with aging and diseases of the elderly, as a separate specialty. He also wrote a thesis demonstrating that gout was a separate disease from rheumatoid arthritis. His focus, however, was on neurological diseases and disorders. When Charcot began his career there was little understanding of the causes of neurological disorders, and very few clusters of symptoms had been identified and attributed to specific underlying causes. Charcot studied and documented the symptoms of patients during their lifetimes then correlated these symptoms with physical changes in their brain, spinal cord, or muscles noted after their deaths in autopsy examination.

Charcot discovered and named many diseases and disorders, including Charcot's Joint, Charcot-Marie-Tooth disease, and amyotrophic lateral sclerosis (ALS, also known as Lou Gehrig's disease), which was for many years known as Charcot's disease. He provided the first clinical description of multiple sclerosis, identified many areas of the brain and their associated functions, and identified miliary aneurysms (bulges in the small blood vessels of the brain that frequently cause stroke). He also devoted much time to the treatment of hysteria, for which he frequently used hypnosis.

In addition to being a renowned and prolific researcher, Charcot was known as a charismatic teacher and lecturer. He created a Tuesday series of clinical talks and demonstrations and a Friday series of lectures on related topics. These were often open to the public and attracted a wide audience. Medical students from all over the world traveled to study with Charcot. George Gilles de la Tourette, Alfred Binet, and Sigmund Freud were among his students.

- using the arms and legs to push and pull against the physician's hands
- passive movement of the joints by the physician and active movement by the patient

Head and facial movement tests may include:

- touching various areas of the face
- biting down
- swallowing
- smiling, grimacing, moving the cheeks, and baring the teeth
- tongue movement
- testing the gag reflex using a tongue blade
- head movements such as turning side to side against mild resistance
- shrugging the shoulders

Tests of coordination, balance, and gait may include:

WWW.BOOKBAZ.IR

- observation of a patient's walk and general coordination
- moving one's finger back and forth between one's nose and the examiner's finger, touching the tip of each
- tapping one's fingers together rapidly in a coordinated manner
- moving one's hands back and forth on top of one another as smoothly as possible
- rubbing one heel smoothly over the other shin
- drawing a spiral
- touching a finger to one's nose with the eyes closed
- balancing with the feet together and eyes closed
- standing with the eyes closed while being gently pushed to one side
- heel-to-toe walking in a straight line
- walking on one's toes
- turning abruptly
- running, hopping, skipping, or jumping
- evaluation of any functional limitations, such as difficulty writing or holding a cup or utensil

Sensory tests may include:

- hearing tests using a ticking watch or a tuning fork
- clarity, fluency, and coherence of speech
- vision tests
- examining the eye with a special light to evaluate the optic nerve
- using a light to evaluate pupil size reflex
- evaluating eye movement by having the patient follow a light or the examiner's finger in various directions with the eyes
- identifying various tastes—such as sweet, sour, and bitter—on the back of the tongue
- identifying different smells with the eyes closed
- identifying objects and sensations—such as sharp or dull—as the physician touches parts of the patient's body with a finger, sharp object, cotton ball, paint brush, dull needle, tuning fork, or alcohol swab
- identifying numbers or letters traced on the body
- using pinpricks to test a patient's pain response on different parts or opposite sides of the body
- using cold or warm objects to test temperature sensations
- sensing a position by identifying the direction in which the examiner is moving a part of the patient's body, such as a big toe

Evaluating mental status is particularly important when other parts of a neurological exam yield normal results. Sometimes small changes in memory or other intellectual abilities are the only indication of a problem. Evaluating mental skills can also be useful for determining a course of treatment and making a prognosis. Mental status tests may involve observing the patient for the following:

- consciousness or awareness of and responsiveness to the environment and the senses
- ability to follow simple and complex directions
- orientation with reference to time, place, and person, such as knowing the current time and date and the current president
- attentiveness
- ability to appropriately answer simple but detailed questions
- ability to read and write
- intellectual capacity, including comprehension, insight, and judgment
- solving simple mathematical problems
- copying a three-dimensional drawing
- drawing a clock with the numbers and hands placed appropriately
- abstract reasoning such as explaining the meaning of common sayings
- memory, such as repeating sentences or a list of objects used early in the exam or describing yesterday's breakfast or what happened on the last holiday
- appearance, mood, and general behavior
- with an infant, observing the child's interaction with parents

Specific components of a neurological exam evaluate the function of each of the 12 cranial nerves:

- cranial nerve I—the olfactory nerve
- cranial nerve II—the optic nerve
- cranial nerve III—the oculomotor nerve responsible for pupil size and eye movement
- cranial nerve IV—the trochlear nerve involved in eye movement
- cranial nerve V—the trigeminal nerve, which has various functions, including the ability to feel the face and inside the mouth and move muscles involved in chewing
- cranial nerve VI—the abducens nerve involved in eye movement
- cranial nerve VII—the facial nerve, which has various functions, including taste and movement
- cranial nerve VIII—the acoustic nerve
- cranial nerve IX—the glossopharyngeal nerve involved in taste

- cranial nerve X—the vagus nerve involved in swallowing, gag reflex, and aspects of taste and speech
- cranial nerve XI—the accessory nerve involved in moving the head and shoulders
- cranial nerve XII—the hypoglossal nerve responsible for tongue movement

A newborn or infant neurological exam evaluates reflexes or automatisms, each of which disappears at a certain stage of normal development. These reflexes include, but are not limited to, the following:

- blinking—closing the eyes in response to a bright light
- Babinski reflex—the toes extending upward as an infant's foot is stroked
- crawling—infants making crawling motions when placed on their stomach
- Moro reflex—infants throwing out their arms, opening their hands, and throwing back their heads when startled or moved rapidly
- palmar and plantar grasps—infants' fingers and toes curling around a nearby finger
- startle reflex—infants extending and flexing the arms with the hands fisted in response to loud noise A measurement of head circumference is also part of a neurological exam in infants and younger children.

Purpose

Neurological exams are performed for a variety of purposes:

- as part of a complete physical exam
- as part of a newborn physical exam
- to assess or follow the effects of a head or spine birth defect
- for the diagnosis of a wide variety of diseases and conditions
- to follow the progression or management of a disease or condition
- to monitor an injury to the head, neck, or back
- to monitor recovery following brain surgery

Neurological exams are routine in some sports, most notably preseason exams for all National Football League players to provide a baseline in case of **concussion**. A neurological exam can reveal signs of increased intracranial pressure or decreased brain function. In addition to concussions, neurological exams are performed on patients with any of the following symptoms:

- fatigue
- headaches
- blurred vision
- fever of unknown origin
- numbness or tingling in the arms or legs
- decreased arm or leg movement
- tremor
- uncontrollable jerky body movements
- problems with balance or coordination
- behavioral changes

A neurological exam is often one of the first procedures in the diagnosis of many diseases and conditions, including the following:

- central nervous system (CNS) infections, such as encephalitis and meningitis
- stroke
- transient ischemic attacks—in which the exam results may be abnormal during the episode but normal immediately afterwards
- bleeding in the brain
- spinal cord injuries
- carotid artery disease
- peripheral neuropathy
- alcoholic neuropathy
- erectile dysfunction
- brain and spinal cord tumors, including pituitary tumors and primary CNS lymphomas
- nasopharyngeal cancer
- brain abscesses
- brain herniation
- epilepsy
- cerebral palsy
- dementia
- Alzheimer's disease
- Parkinson's disease
- Huntington's disease
- multiple sclerosis
- myasthenia gravis—a muscle weakness disorder
- neurological complications of HIV/AIDS
- systemic lupus erythematosus, a chronic inflammatory autoimmune disease
- amyotrophic lateral sclerosis (ALS)
- congenital toxoplasmosis
- craniosynostosis, a congenital defect in which one or more sutures on a infant's head close too early
- mitochondrial diseases
- motor neuron diseases
- metabolic diseases of muscle

WWW.BOOKBAZ.IR

KEY TERMS

Automatism—An automatic action or reflex.

Babinski reflex—A reflex movement by the big toe when the sole is tickled; an upward response is normal in infancy, but indicates central nervous system damage in older children and adults.

Moro reflex—A reflex startle reaction in infants; the arms and legs move away from the body and to the side and are then drawn together.

Ophthalmoscope—An instrument for viewing the interior of the eye.

Stroke—A sudden diminishment of consciousness, sensation, or voluntary movement caused by a rupture or clot in a blood vessel in the brain.

Tendon reflex—A reflex action, such as a knee jerk, in which a light blow to the tendon causes the muscle to contract.

Results

A neurological exam is a relatively simple, quick, and inexpensive means of identifying a wide range of neurological abnormalities. In many cases a simple neurological exam has been found to be superior to expensive computed tomography (CT) scans for diagnoses. Neurological problems and nervous system damage can cause delays in infant and child development and functioning: Early diagnosis of problems using a neurological exam can help identify the cause and decrease the likelihood of long-term complications.

Precautions

Precautions concerning a neurological exam include:

- The exam requires skill and patience on the part of the physician.
- Importantly, the exam requires the patient's cooperation.
- Responses can be affected by the wakefulness, awareness, and alertness of the patient, so the mental status portion of a neurological exam is usually performed early on.
- The sensory exam should be repeated for accuracy.

Aftercare

There are no special preparations or risks involved in a neurological exam. However abnormal results may require further procedures such as a CT scan, **magnetic resonance imaging** (MRI), x rays, or laboratory tests. The patient may be referred to a neurologist or other specialist.

Neuropsychological testing

Definition

Clinical neuropsychology is a field with historical origins in both psychology and neurology. The primary activity of neuropsychologists is assessment of brain functioning through structured and systematic behavioral observation. Neuropsychological tests are designed specifically to examine a variety of cognitive abilities, including speed of information processing, attention, memory, language, and executive functions,

which are necessary for goal-directed behavior. Such scientifically validated tests are administered generally to individuals to evaluate brain functions. These tests cover a wide range of mental processes from simple motor performance to complex problem solving and reasoning.

By testing a range of cognitive abilities and examining patterns of performance in different cognitive areas, neuropsychologists can make inferences about underlying brain function, including its structure and pathway. Consequently, neuropsychological testing is a primary way that neuropsychologists and other scientists assess neuropsychological function in humans.

Purpose

Neuropsychological testing is an important component of the assessment and treatment of **traumatic brain injury**, attention deficits, developmental milestone failures (in children), **dementia**, neurological conditions, psychiatric disorders, drug or alcohol abuse, and other such problems. Neuropsychological testing is also an important tool for examining the effects of toxic substances and medical conditions on brain functioning.

Testing helps to assess such functions as working memory and attention, short-term and long-term memory, processing speed, reasoning and problem-solving ability, ability to understand and express language, visual-spatial organization, visual-motor coordination, and planning and organizational abilities.

Description

Neuropsychological testing is based on psychometric theory. A sample from a general population (control group) is used as the foundation for scoring, with individual scores compared to the normalized sample.

Origins

As early as the seventeenth century, scientists theorized about associations between regions of the brain and specific functions. French philosopher René Descartes (1596–1650) believed the human soul could be localized to a specific brain structure, the pineal gland. In the eighteenth century, Austrian physiologist Franz Joseph Gall (1758–1828) advocated the theory that specific mental qualities such as spirituality or aggression were governed by discrete parts of the brain. In contrast, French physiologist Marie Jean Pierre Flourens (1794–1867) contended that the brain was an integrated system that governed cognitive functioning in a holistic manner.

Later discoveries indicated that brain function is both localized and integrated. French physician Pierre Paul Broca (1824–1880) and German physician Karl Wernicke (1848–1905) furthered understanding of localization and integration of function when they reported the loss of language abilities in patients with lesions to two regions in the left hemisphere of the brain.

The modern field of neuropsychology emerged in the twentieth century, combining theories based on anatomical observations of neurology with the techniques of psychology, including objective observation of behavior and the use of statistical analysis to differentiate functional abilities and define impairment. Soviet neuropsychologist Alexander Romanovich Luria (1902–1977) played a major role in defining neuropsychology as it is practiced today. Luria formulated two principal goals of neuropsychology: to localize brain lesions and analyze psychological activities arising from brain function through behavioral observation.

American neuropsychologist Ralph M. Reitan later emphasized the importance of using standardized psychometric tests to guide systematic observations of brain-behavior relationships. Specifically, Dr. Reitan and Dr. Ward Halstead co-developed the Halstead-Reitan Battery—one of many neuropsychological tests used commonly in the twenty-first century—which is used to evaluate brain and nervous system function in individuals 15 years of age and older.

Applications

Before the introduction of neuroimaging techniques such as computed tomography (CT), **magnetic resonance imaging** (MRI), **electroencephalography** (EEG), and **positron emission tomography** (PET), neuropsychological testing was the only way for clinicians to evaluate the condition of the living brain. These neuroimaging techniques allow for the observation of brain lesions or structural abnormalities in living patients. Today, neuropsychological testing and neuroimaging techniques are used together to determine which part of the brain is affected in a given patient.

Neuropsychological tests can identify syndromes associated with problems in a particular area of the brain. For instance, a patient who performs well on tests of attention, memory, and language, but poorly on tests that require visual spatial skills, such as copying a complex geometric figure or making designs with colored blocks, may have dysfunction in the right parietal lobe, the region of the brain involved in

WWW.BOOKBAZ.IR

complex processing of visual information. When a patient complains of problems with verbal communication after a **stroke**, separate tests that examine production and comprehension of language help neuropsychologists identify the location of the stroke in the left hemisphere. Neuropsychological tests can also be used as screening tests to see whether more extensive diagnostic evaluation is appropriate. Neuropsychological screening of elderly people complaining of memory problems can help identify those at risk for dementia versus those experiencing normal age-related **memory loss**.

As neuropsychological testing came to play a less vital role in localization of brain dysfunction, clinical neuropsychologists found new uses for their skills and knowledge. By clarifying which cognitive abilities are impaired or preserved in patients with brain injury or illness, neuropsychologists can predict how well individuals will respond to different forms of treatment or **rehabilitation**. Although patterns of test scores illustrate profiles of cognitive strength and weakness, neuropsychologists can also learn a great deal about patients by observing how they approach a particular test. For example, two patients can complete a test in very different ways yet obtain similar scores. One patient may work slowly and methodically, without making errors, while another rushes through the test, making several errors, but quickly correcting them. Some individuals persevere despite repeated failure on a series of test items, while others refuse to continue after a few failures. These differences might not be apparent in test scores but can help clinicians choose among rehabilitation and treatment approaches.

Performance on neuropsychological tests is usually evaluated through comparison to the average performance of large samples of normal individuals. Most tests include tables of these normal scores, often divided into groups based on demographic variables, like age and education, that appear to affect cognitive functioning. This allows individuals to be compared to appropriate peers.

Evaluation

The typical neuropsychological examination evaluates sensation and perception, gross and fine motor skills, basic and complex attention, visual spatial skills, receptive and productive language abilities, recall and recognition memory, and executive functions such as cognitive flexibility and abstraction. Motivation and personality are often assessed as well, particularly when clients are seeking financial compensation for injuries, or cognitive complaints are not typical of the associated injury or illness.

Test methods

Some neuropsychologists prefer to use fixed test batteries, like the Halstead-Reitan Battery or the Luria-Nebraska Battery, for all patients. These batteries include tests of a wide range of cognitive functions, and those who advocate their use believe that all functions must be assessed in each patient in order to avoid diagnostic bias or failure to detect subtle problems. The more common approach today, however, is to use a flexible battery based on hypotheses generated through a clinical interview, observation of the patient, and review of medical records.

While the flexible approach to neuropsychological testing is more prone to bias, it has the advantage of preventing unnecessary testing. Since patients often find neuropsychological testing stressful and fatiguing, and these factors can negatively influence performance, advocates of the flexible battery approach argue that tailoring test batteries to particular patients can provide more accurate information. Moreover, because insurance companies generally have a fixed amount for reimbursement of psychological testing, a more focused approach may assist in payment for testing services.

Numerous neuropsychological tests are available. Some of the more popular ones include (in alphabetical order):

- Ammons Quick Test
- Beck Depression Inventory and Beck Anxiety Inventory
- Clinical Dementia Rating
- Cognitive Assessment Screening Instrument
- Continuous Performance Task
- Finger Tapping Test
- Halstead-Reitan Battery
- Kaufman Assessment Battery for Children
- Luria-Nebraska Battery
- Minnesota Multiphasic Personality Inventory
- Repeatable Battery for the Assessment of Neuropsychological Status
- Rorschach Projective Technique
- Shipley Institute of Living Scale
- Test of Memory and Learning
- Wechsler Adult Intelligence Scale and Wechsler Intelligence Scale for Children
- Wide Range Achievement Test
- Wonderlic Personnel Test
- Word Memory Test

KEY TERMS

Dementia—The progressive deterioration of intellectual functions, such as memory, within the brain. Alzheimer's disease is a type of dementia.

Psychiatric—Relating to psychiatry.

Psychometric—A branch of psychology that deals with measurement of mental capacities, processes, and traits.

Visual-motor—The ability to coordinate vision and bodily movements.

Visual-spatial—The ability to manipulate multidimensional figures mentally.

Results

The results of neuropsychological testing are used as a primary way to assess neuropsychological function in humans. Testing includes scores, behavior observations, distinct and consistent patterns, and clinical history, which are all used in combination to provide a final assessment of individuals. Results in neuropsychological testing can be affected due to an individual's age, education, gender, and cultural background.

Different tests may differ based on validity, reliability, sensitivity, and specificity. Validity refers to the degree by which a test measures what it intended to measure. Reliability refers to the consistency and accuracy of the test; that is, how well scores remain consistent when extraneous variables are present (such as illness or injury). Sensitivity refers to the ability of the test to measure abnormalities, while specificity refers to the ability of the test to distinguish individuals with a specific abnormality from other individuals without such abnormality or with other types of abnormalities.

Risks

Neuropsychological testing runs the risk of being biased if a trained and experienced administrator is not used. Therefore, neuropsychological testing should be carried out by a licensed psychologist trained in neuropsychology. When qualified personnel are used to collect behavioral, cognitive, language, and executive functioning skills, such data can lead to an accurate diagnosis of the individual.

Neurosurgery

Definition

Neurosurgery is a specialized field of surgery for the treatment of diseases or conditions of the central nervous system (CNS) and spine.

Description

Neurosurgery is the specialized field of surgery that treats diseases that affect the CNS—the brain and the spine. A neurosurgeon is a medical doctor who has received extensive training in the surgical and medical management of neurological diseases.

WWW.BOOKBAZ.IR

KEY TERMS

Cerebral aneurysms—A sac in a brain artery that can rupture and cause bleeding in the brain.

Craniosynostosis—Premature closure of the skull, which results in skull deformities.

Craniotomy—Procedure to remove a lesion in the brain through an opening in the skull.

Desiccation—Tissue death.

Encephaloceles—Protrusion of the brain through a defect in the skull.

Germinoma—A tumor of germ cells (ovum and sperm cells that participate in production of the developing embryo).

Hydrocephalus—A defect characterized by an increase in cerebrospinal fluid (CSF), which bathes and nourishes the brain and spinal cord.

Intraventricular hemorrhage—Hemorrhage in the ventricles of the brain.

Lymphoma—A tumor of lymph glands or lymph tissues.

Meninges—Membranes that cover the brain.

Myelomeningoceles (MMC)—A protrusion in the vertebral column containing spinal cord and meninges.

Subarachnoid space—A space between membranes that covers and protects the brain.

The field of neurosurgery is one of the most sophisticated surgical specialties and encompasses advanced surgical and imaging technology and new research in molecular neurosurgery and **gene therapy**. There are five general categories of neurosurgical diseases that are commonly managed by neurosurgeons: cerebrovascular (hemorrhage [bleeding] and aneurysms); **traumatic brain injury** (TBI, traumatic injury caused by accident); degeneration diseases of the spine; tumors in the CNS; functional neurosurgery; surgery for congenital abnormalities; and neurosurgical management of the CNS.

Cerebrovascular diseases that usually require surgery include spontaneous intracranial hemorrhage (bleeding within the skull), spontaneous **subarachnoid hemorrhage** (bleeding beneath the outer membranous covering of the brain), spontaneous intracerebral hemorrhage (bleeding within the brain), cerebral aneurysms (outpouchings of the blood vessel), and vascular malformations.

Brain hemorrhage

Spontaneous intracranial hemorrhage is a condition characterized by hemorrhage in the brain (hemorrhagic **stroke**) that results in a sudden onset of neurologically worsening symptoms (that include focal neurologic deficits and loss of consciousness). CT scans are helpful in identifying the intracranial hemorrhage, of which there are several types depending on the location. These include epidural hemorrhage (bleeding between the skull and the dura mater), subdural hemorrhage (bleeding between the dura mater and the subarachnoid membrane), subarachnoid hemorrhage (bleeding between the subarachnoid membrane and the pia mater), intracerebral hemorrhage, and intraventricular hemorrhage (bleeding into the cerebrospinal fluid spaces or ventricles of the brain).

A spontaneous subarachnoid hemorrhage is defined as blood (not caused by **trauma**), in the subarachnoid space. The amount of blood in the subarachnoid space can be a focal (small area) amount or a larger, more diffuse hemorrhage, which can be further complicated by having an intraventricular hemorrhage or intracerebral hematoma at the same time.

(Spontaneous subarachnoid hemorrhage is most commonly caused by a **cerebral aneurysm**. The aneurysm can be identified using a CT or MR angiogram or catheter angiogram. One method of obliterating the aneurysm is by using a procedure called "clipping." A **craniotomy** is performed using microsurgical techniques. An operative microscope helps to identify the aneurysm, which is then clipped. Berry, or congenital aneurysm, is the reason for over half of all cases of spontaneous subarachnoid hemorrhage.

A spontaneous intracerebral hemorrhage (or hematoma) (SICH) is a blood clot in brain tissue that can arise abruptly and is strongly correlated with **hypertension**. Surgery is done when there is rapid increase in the intracranial pressure leading to brain herniation or brain-stem compression. The aim of surgery is primarily to relieve pressure by making a large opening in the skull and/or by removing the blood from the brain tissue.

Severe **head injury** is defined as an injury that produces **coma** (patient will not open eyes even to painful stimulus, is incapable of following simple commands, and is unable to utter words). These clinical criteria are defined on the well-established Glasgow Coma Scale (GCS). A **physical examination** and neurologic assessment by a neurosurgeon and brain scan imaging (CT scan) are necessary for the initial evaluation. The neurosurgeon can place a special catheters to monitor intracranial

pressure (due to brain swelling) and also to drain cerebrospinal fluid (e.g., external ventricular drain).

Tumors inside the brain (intracranial tumors) are typically of two types, primary and secondary intracranial tumors. Primary intracranial tumors (PICT) rarely metastasize and usually originate in the brain, coverings (membranes) of the brain, or the pituitary gland.

Secondary intracranial tumors arise from outside the brain coverings (meninges). Quite commonly, secondary intracranial tumors are bloodborne metastatic disease from primary malignant cancer outside the brain (i.e., cancer from some other location that has spread to the brain). The most common sites that spread to the brain include breast, kidney, lung, and skin (specifically malignant melanoma).Approximately 250,000 persons per year are affected by secondary intracranial tumors. A tumor in the brain can cause increased intracranial pressure, or cause symptoms associated with localized compression of the brain (i.e., a tumor grows and compresses part of the brain against the skull). One common cause of increased intracranial pressure is growth of a tumor that obstructs the duct system of cerebrospinal fluid (CSF), which bathes and nourishes the brain and spinal cord. Common symptoms can include nausea, **vomiting**, **headache** that is worse in the morning, and a reduced level of consciousness that causes drowsiness. Tumors causing focal compression on or irritation of the brain usually result in loss of neurologic function. This progressive loss of neurologic function can manifest as **tinnitus** (ringing in the ears) or **aphasia** (language problems).

Technical advancement has made surgical removal of brain tumors more effective and safer. Surgical management of intracranial tumors focuses on diagnosis and reduction of tumor mass. Depending on tumor location and patient health status, the neurosurgeon may perform a needle biopsy (called image-directed stereotactic needle biopsy) or a craniotomy to extract a piece of tumor for pathologic analysis. If the tumor is located in an area where surgery can be performed, the neurosurgeon generally will remove the mass if the patient can tolerate general **anesthesia**. Exceptions to a surgical option may be exercised to treat malignant tumors that are very sensitive to **chemotherapy** or **radiation therapy** (e.g., to manage lymphoma or germinoma). One of the most common types of tumors is the glioma, which accounts for 30% of all primary brain tumors and 80% of all primary brain tumors.

Degenerative disorders of the spine

Degenerative disorders of the spine are a common problem. Between 50% and 90% of the population will experience back **pain** at some point in their lifetime. Most of these symptoms subside on their own within a few weeks; the cost, however, is realized in decreased productivity and lost wages—a **public health** problem. Pain in the lumbar spine is the most common reason adults seek medical attention. Lower back disorders are among the most frequent reasons for referral to a neurosurgeon. Lumbar discs are prone to herniation and desiccation (drying out) as a result of the heavy load they bear and the motion to which they are subject. Nerves that run from the vertebrae extend out to distant body parts, and degeneration of the discs may change bony structures in such a manner that can cause nerve compression. Typically, patients with degenerative disorders of the spine may experience pain, numbness, paresthesia (tingling), and restriction of neck movement (if the affected vertebra is in the cervical spine, which is located in the back of the neck). Neurosurgery for degenerative disc disease includes removal of the diseased intervertebral discs and fusing the vertebral bodies/stabilizing the vertebral bodies. This can be accomplished by microdiskectomy or open surgery.

Surgery for congenital abnormalities

Congenital abnormalities arise during embryonic development. Important changes in growth and chemistry occur during the second week of human gestation; these changes contribute to the development of the nervous system. Several different types of cells proliferate as they move together or separate into other structures according to an orchestrated, natural timeline. Defects can occur at different stages of development. Among the defects with which infants can be born include myelomeningoceles, encephaloceles, **hydrocephalus**, and craniosynostosis. Neurosurgery can be undertaken to repair these defects.

Central nervous system infections

Solitary or multiple brain abscesses can occur as a result of infection in the brain. Patients present with clinical symptoms such as focal (a specific area is affected) neurologic signs, seizures, altered mental status, and increased intracranial pressure. CT scans and **magnetic resonance imaging** (MRI) are helpful for identification of brain abscesses. Surgery is usually indicated if the **abscess** fails to resolve or worsens following antibiotic treatment, or if there are signs of mass effect and brain herniation. Although rare, a spinal epidural abscess can occur. Typically, bacteria can spread in patients who have acute bacterial **meningitis** (infection of the subarachnoid spaces and meninges). The specific type of bacteria varies according to the patient's age.

WWW.BOOKBAZ.IR

Functional neurosurgery

Functional neurosurgery is a special type of surgical procedure used to manage movement disorder, **epilepsy**, and pain. Stereotactic neurosurgery makes use of a coordinate system that provides accurate navigation to a specific point or region in the brain. This is usually done by placing and fixing into position a frame on the scalp (using four threaded pins that penetrate the outer skull to stabilize the frame in position) under local anesthesia. A special box and stereotactic arc are placed to precisely determine X, Y, and Z coordinates of any point within the frame.

Epilepsy surgery

Approximately 70 per 100,000 people in the United States takes antiepileptic medications for seizure disorders. The risk of developing epilepsy over a lifetime is 3%, and there are 200,000 new cases diagnosed per year, 45,000 in children under the age of fifteen. The majority of cases (approximately 60,000) are epilepsy of the temporal lobe (the brain lobes located on the sides of the head). Approximately 30% of patients with epilepsy are unable to have their seizures adequately controlled through medications. Half of these patients (about 100,000 annually) are evaluated to see if they might be candidates to have surgery to control their seizures, but only about 3,000 actually have epilepsy surgery. The patient and neurosurgeon should consider surgery if continued seizures cause injuries due to repeated falls; driving restrictions; limitation of social interactions; problems related to education and learning; and employment limitations.

The future of neurosurgery

Neurosurgery as a field is faced with many new opportunities and challenges, based on advanced technological approaches and molecular approaches to neurosurgical problems. Advances in technology have allowed the neurosurgeon to precisely locate abnormal tissue in the brain and spinal cord, thereby preserving normal tissues from surgical trauma. In addition to cardiovascular neurosurgery, functional neurosurgery, neuro-oncologic neurosurgery (surgical removal of brain tumors), and spinal surgery, the future holds many new research innovations. The field of molecular neurosurgery can make it possible to introduce genetic material into nerve cells and to redirect protein synthesis—to work toward reversing the disease process, in general.

Neutropenia

Definition

Neutropenia is an abnormally low level of neutrophils in the blood. Neutrophils are white blood cells (WBCs) produced in the bone marrow that ingest bacteria. Neutropenia is sometimes called agranulocytosis or granulocytopenia because neutrophils make up about 60% of WBCs and have granules inside their cell walls. Neutropenia is a serious disorder because it makes the body vulnerable to bacterial and **fungal infections**.

KEY TERMS

Cyclical neutropenia—A rare genetic blood disorder in which the patient's neutrophil level drops below 500/mm^3 for six to eight days every three weeks.

Differential—A blood cell count in which the percentages of cell types are calculated as well as the total number of cells.

Felty's syndrome—An autoimmune disorder in which neutropenia is associated with rheumatoid arthritis and an enlarged spleen.

Granulocyte—Any of several types of white blood cells that have granules in their cell substance. Neutrophils are the most common type of granulocyte.

Neutrophil—A granular white blood cell that ingests bacteria, dead tissue cells, and foreign matter.

Sargramostim—A medication made from yeast that stimulates WBC production. It is sold under the trade names Leukine and Prokine.

Sequestration and margination—The removal of neutrophils from circulating blood by cell changes that trap them in the lungs and spleen.

Description

The normal level of neutrophils in human blood varies slightly by age and race. Infants have lower counts than older children and adults, and African Americans have lower counts than Caucasians or Asians. The average adult level is 1,500 cells/mm^3 of blood. Neutrophil counts (in cells/mm^3) are interpreted as follows:

- greater than 1,000–normal protection against infection
- 500–1,000–some increased risk of infection
- 200–500–great risk of severe infection
- lower than 200–risk of overwhelming infection; requires hospital treatment with antibiotics

Causes and symptoms

Neutropenia may result from three processes:

DECREASED WBC PRODUCTION. Lowered production of white blood cells is the most common cause of neutropenia. It can result from:

- medications that affect the bone marrow, including cancer drugs, chloramphenicol (Chloromycetin), anticonvulsant medications, and antipsychotic drugs (Thorazine, Prolixin, and other phenothiazines)
- hereditary and congenital disorders that affect the bone marrow, including familial neutropenia, cyclic neutropenia, and infantile agranulocytosis
- cancer, including certain types of leukemia
- radiation therapy
- exposure to pesticides
- vitamin B_{12} and folate (folic acid) deficiency

DESTRUCTION OF WBCS. WBCs are used up at a faster rate by:

- acute bacterial infections in adults
- infections in newborns
- certain autoimmune disorders, including systemic lupus erythematosus (SLE)
- penicillin, phenytoin (Dilantin), and sulfonamide medications (Benemid, Bactrim, Gantanol)

SEQUESTRATION AND MARGINATION OF WBCS. Sequestration and margination are processes in which neutrophils are removed from the general blood circulation and redistributed within the body. These processes can occur because of:

- hemodialysis
- Felty's syndrome or malaria, in which the neutrophils accumulate in the spleen
- bacterial infections, in which the neutrophils remain in the infected tissues without returning to the bloodstream

Neutropenia has no specific symptoms except the severity of the patient's current infection. In severe neutropenia, the patient is likely to develop **periodontal disease**, oral and rectal **ulcers**, **fever**, and bacterial **pneumonia**. Fever recurring every 19–30 days suggests cyclical neutropenia.

Diagnosis

Diagnosis is made on the basis of a **white blood cell count and differential** (determines the percentage of different types of WBCs). The cause of neutropenia is often difficult to establish and depends on a combination of the patient's history, genetic evaluation, bone marrow biopsy, and repeated measurements of the WBCs.

Treatment

Treatment of neutropenia depends on the underlying cause.

WWW.BOOKBAZ.IR

Medications

Patients with fever and other signs of infection are treated for seven to 10 days with **antibiotics**. Nutritional deficiencies are corrected by green vegetables to supply **folic acid**, and by vitamin B supplements.

Medications known to cause neutropenia are stopped. Neutropenia related to pesticide exposure is treated by removing the patient from the contaminated environment.

Patients receiving **chemotherapy** for cancer may be given a blood growth factor called sargramostim (Leukine, Prokine) to stimulate WBC production.

Surgery

Patients with Felty's syndrome who have repeated infections may have their spleens removed.

Prognosis

The prognosis for mild or chronic neutropenia is excellent. Recovery from acute neutropenia depends on the severity of the patient's infection and the promptness of treatment.

Nicotine and related disorders

Definition

Nicotine is the main psychoactive ingredient in tobacco. It is a physically and psychologically addictive drug. Nicotine is the most influential dependence-producing drug in the United States and worldwide, and its use is associated with many serious health risks.

Description

Nicotine is the most addictive and psychoactive chemical in tobacco, a plant native to North America. Early European explorers learned to smoke its leaves from indigenous peoples who had been using tobacco for hundreds of years. They took tobacco back to Europe, where it became immensely popular. Tobacco became a major source of income for the American colonies and later for the United States. Advances in cigarette-making technology caused a boom in cigarette **smoking** in the early 1900s. Before the early twentieth century, most people who used tobacco used pipes, cigars, or chewing tobacco.

In the 1950s, researchers began to link cigarette smoking to certain respiratory diseases and cancers. In 1964, the Surgeon General of the United States issued the first health report on smoking. Cigarette smoking peaked in the United States in the 1960s then began to decline as health concerns about tobacco increased. In 1971, cigarette advertising was banned from television, although tobacco products continued to be advertised in other media.

Nicotine effects and trends

Effects:

- Nicotine is highly addictive.
- The tar in cigarettes increases a person's chance of developing lung cancer, emphysema, or chronic bronchitis.
- The carbon monoxide in smoke increases the risk of developing a cardiovascular disease.
- Pregnant smokers are more likely to have miscarriages or babies born with low birth weights.
- Secondhand smoke can cause lung cancer in adults and greatly increases the risk of respiratory illnesses in children.

Statistics and trends:

In 2011, more than 68 million Americans aged 12 and older used a tobacco product at least once in the past month.

- Almost 57 million smoked cigarettes
- More than 8.2 million used smokeless tobacco
- More than 12.9 million smoked cigars
- More than 2.1 million smoked pipe tobacco

Nicotine replacement gum. *(© Image Point Fr/ Shutterstock.com)*

Pure nicotine is a colorless liquid that turns brown and smells like tobacco when exposed to air. Nicotine can be absorbed through the skin, the lining of the mouth and nose, and the moist tissues lining the lungs. Cigarettes are the most efficient nicotine delivery system. Once tobacco smoke is inhaled, nicotine reaches the brain in less than 15 seconds. Because people who smoke pipes and cigars do not inhale, they absorb nicotine more slowly. Nicotine in chewing tobacco and snuff is absorbed through the mucous membranes lining the mouth and nasal passages. There are also several "hard snuff" and other new tobacco products being produced and marketed as alternative to traditional tobacco products. At least one study of the nicotine content of these products has found that some have lower levels of nicotine than regular tobacco products, but others contain comparable levels.

Demographics

There were about 42.1 million adult smokers in the United States in 2014, that is, approximately 18.1% of adults, 18 years or older.

The prevalence of smoking gradually decreased in the United States and many other industrialized countries beginning in the 1970s, but the use of tobacco products rapidly increased in developing nations, where approximately 80% of current smokers live. Younger populations may be particularly vulnerable. For example, a CDC survey from 2003 found that almost 42% of teenaged boys in one city in Mali were cigarette smokers. The World Health Organization attributed more than 5 million deaths per year globally to tobacco use among the estimated one billion smokers worldwide, a death total expected to increase to 8 million by 2030. Another 600,000 deaths occur among nonsmokers as a result of exposure to secondhand smoke. Use of tobacco products in developing countries is of particular concern, because these countries often lack adequate healthcare resources to treat smoking-related diseases, let alone support smoking cessation programs.

KEY TERMS

Cold turkey—A slang term for stopping the use of nicotine (or any other addictive drug) suddenly and completely.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses and helps to regulate movement and emotions.

Epinephrine—Also known as adrenaline, the hormone secreted by the adrenal glands in response to stress.

Neurotransmitter—One of a group of chemicals secreted by a nerve cell (neuron) to carry a chemical message to another nerve cell, often as a way of transmitting a nerve impulse. Examples of neurotransmitters include acetylcholine, dopamine, serotonin, and norepinephrine.

Plaque—A sticky cholesterol-containing substance that builds up on the walls of blood vessels, reducing or blocking blood flow.

Tolerance—A progressive decrease in the effectiveness of a drug with long-term use, requiring higher doses to achieve the desired effect.

Withdrawal—Symptoms experienced by a person who has become physically dependent on a drug, experienced when the drug use is discontinued.

In the United States, men are more likely to smoke than women (33.7% to 21.5%). In developing countries, male smokers outnumber women smokers, but among adolescent populations, girls and boys are about equal in their rates of smoking. In the United States, people who smoke tend to have less formal education than those who do not, with the lowest smoking rates in persons with college degrees. At least 50% of patients diagnosed with psychiatric problems are smokers, whereas more than three-fourths of those who abuse other substances also smoke.

According to the National Survey on Drug Use and Health, from 1997 to 2010, smoking among U.S. middle- and high-school students declined after increasing dramatically in the 1990s. Smoking is most prevalent among adults aged 18 to 25, with an estimated 40.8% of all smokers falling within this age group.

WWW.BOOKBAZ.IR

Nicotine replacement patch helps curb withdrawal symptoms. *(© Image Point Fr/Shutterstock.com.)*

The good news is that in the United States between 2005 and 2012 those who smoked decreased from 20.9% to 18.1% of the population. Nonetheless, smoking is the leading cause of preventable death in the United States: 480,000 deaths from smoking-related problems occur annually, or one in five deaths every year is caused by smoking.

Research suggests that there may be a genetic component to nicotine dependence, just as there is for alcohol dependence. Studies show that girls (but not boys) whose mothers smoked during **pregnancy** are four times more likely to smoke than those whose mothers were tobacco-free during pregnancy. Other research suggests that the absence of a certain enzyme in the body protects the body against nicotine dependence.

Causes and symptoms

How nicotine works

Nicotine is the main addictive drug among the 4,000 compounds found in tobacco smoke. Other substances in smoke such as tar and carbon monoxide present documented health hazards, but they are not addictive and do not cause cravings or withdrawal symptoms to the extent that nicotine does. Neuroimaging technology has shown that levels of monoamine oxidase, the enzyme responsible for boosting mood-enhancing molecule levels in the brain, increase in response to smoking, even though nicotine does not affect levels of this enzyme. Thus, some other compound in cigarette smoke must be acting to exert this effect. In addition, the compound in cigarette smoke acetaldehyde may contribute to tobacco **addiction** and may have a stronger effect in adolescents.

Nicotine is both a stimulant and a sedative. It is a psychoactive drug, meaning that it works in the brain, alters brain chemistry, and changes mood. Once tobacco smoke is inhaled, nicotine passes rapidly through the linings of the lungs and into the blood. It quickly circulates to the brain where it stimulates release of dopamine, a neurotransmitter (nerve signaling molecule) that affects mood. Drugs that elicit an increase in dopamine influence the brain's reward pathway, causing the user to turn again to the drug for another pleasurable, rewarding dopamine response. This release accounts for the pleasurable sensation that most smokers feel almost as soon as they light a cigarette. Nicotine also decreases anger and increases the efficiency of a person's performance on long, dull tasks.

As nicotine affects the brain, it also stimulates the adrenal glands. The adrenal glands are small, pea-sized organs located above each kidney that act as two different endocrine organs. The adrenal gland produces several hormones in the medulla, or inner layer, including epinephrine, also called adrenaline. Under normal circumstances, adrenaline is released in response to **stress** or a perceived threat. It is sometimes called the fight-or-flight hormone, because it prepares the body for action. When adrenaline is released, blood pressure, heart rate, blood flow, and oxygen use increase. Glucose, a simple form of sugar used by the body, floods the body to provide extra energy to muscles. The overall effect of the release of the stress hormones is strain on the cardiovascular (heart and blood vessels) system. This response to stress produces inflammation in the blood vessels that ultimately results in buildup of plaque, which can block the vessels and cause **stroke** or **heart attack**.

Most people begin smoking between the ages of 12 and 20. Few people start smoking as adults over 21. Adolescents who smoke tend to begin as casual smokers, out of rebellion or a perceived need for social acceptance. Dependence on nicotine develops rapidly, however; one study suggests that 85%–90% of adolescents who smoke four or more cigarettes become

regular smokers. Nicotine is addictive, so being tobacco-free soon feels uncomfortable for users. In addition, smokers quickly develop tolerance to nicotine. Tolerance is a condition that occurs when the body needs a larger and larger dose of a substance to produce the same effect. For smokers, tolerance to nicotine means more frequent and more rapid smoking. Soon most smokers develop physical withdrawal symptoms when they try to stop smoking. Users of other forms of tobacco experience the same effects; however, the delivery of nicotine is slower and the effects may not be as pronounced.

Nicotine dependence

In addition to the physical dependence caused by the actions of nicotine on the brain, there is a strong psychological component to the dependency of most users of tobacco products, especially cigarette smokers. Most people who start smoking or using smokeless tobacco products do so because of social factors. These include:

- desire to fit in with peers
- acceptance by family members who use tobacco
- rebelliousness
- association of tobacco products with maturity and sophistication
- positive response to tobacco advertising

Such personal factors as mental illness (depression, **anxiety**, **schizophrenia**, or **alcoholism**), the need to reduce stress and anxiety, or a desire to avoid weight gain also influence people to start smoking. Once smoking has become a habit, whether physical addiction occurs or not, psychological factors play a significant role in a person's continuing to smoke. People who want to stop smoking may be discouraged from doing so because of the following:

- they live or work with people who smoke and who are not supportive of their quitting
- they believe they are incapable of quitting
- they perceive no health benefits to quitting
- they have tried to quit before and failed
- they associate cigarettes with specific pleasurable activities or social situations that they are not willing to give up
- they fear gaining weight

Successful smoking cessation programs must treat both the physical and psychological aspects of nicotine addiction.

Nicotine withdrawal

The American Psychiatric Association first recognized nicotine dependence and nicotine withdrawal as serious psychological problems in 1980. In the early 2000s nicotine is considered an addictive drug, although a common and legalized one.

Quitting nicotine can be difficult. Among people who try, between 75% and 80% relapse within six months. Because of this rate, research has found that smoking cessation programs that last longer than six months can greatly enhance quit rates, achieving rates as high as 50% at one year. Combining a nicotine-withdrawal product with a behavioral-modification or support program has produced the greatest success rates.

The combination of physiological and psychological factors make withdrawal from nicotine very difficult. Symptoms of nicotine withdrawal include:

- irritability
- restlessness
- increased anger or frustration
- sleep disturbances
- inability to concentrate
- increased appetite or desire for sweets
- depression
- anxiety
- constant thoughts about smoking
- cravings for cigarettes
- decreased heart rate
- coughing

Withdrawal symptoms are usually more pronounced in smokers than in those who use smokeless tobacco products, and heavy smokers tend to have more symptoms than light smokers when they try to stop smoking. People with depression, schizophrenia, alcoholism, or **mood disorders** may find it especially difficult to quit, as nicotine offers temporary relief for some of the symptoms of these disorders.

Symptoms of nicotine withdrawal begin rapidly and peak within one to three days. Withdrawal symptoms generally last three to four weeks, but a significant number of smokers have withdrawal symptoms lasting longer than one month. Some people have strong cravings for tobacco that last for months, even though the physical addiction to nicotine is gone. These cravings often occur in settings in which the person formerly smoked, such as at a party, while driving, or after a meal. Researchers believe that much of this extended craving is psychological.

WWW.BOOKBAZ.IR

Diagnosis

Smokers usually self-diagnose their nicotine dependence and nicotine withdrawal. Such questionnaires as the Fagerstrom Test for Nicotine Dependence (FTND), a short six-item assessment of cigarette use, help to determine the level of tobacco dependence. Physicians and mental health professionals are less concerned with diagnosis, which is usually straightforward, than with determining the physical and psychological factors in each patient that must be addressed for successful smoking cessation.

The Diagnostic and Statistical Manual of Mental Disorders, the handbook used by medical professionals in diagnosing mental health conditions, recognizes two smoking-related disorders: tobacco use disorder and tobacco withdrawal disorder. The criteria for diagnosing a tobacco use disorder are the same for any substance abuse disorder. Specific criteria include experiencing symptoms of tolerance or withdrawal, unsuccessful attempts at quitting, and smoking for longer or more often than was originally intended. Criteria for tobacco withdrawal include experiencing withdrawal symptoms within 24 hours after quitting (or reducing intake).

Treatment

Most people do not decide to stop smoking all of the sudden. Instead, they go through several preparatory stages before taking action. First is the precontemplation stage, in which the smoker does not even consider quitting. Precontemplation is followed by the contemplation stage, in which the smoker thinks about quitting but takes no action. Contemplation eventually turns to preparation, often when counselors or family members encourage or urge the smoker to quit. Now the smoker starts making plans to quit soon. Finally the smoker arrives at the point of taking action.

Having decided to stop smoking, a person has many choices of programs and approaches. When mental health professionals are involved in smoking cessation efforts, one of their first jobs is to identify the physical and psychological factors that keep the person smoking. This identification helps to direct the smoker to the most appropriate type of program. Assessment examines the frequency of the person's smoking, social and emotional attachment to cigarettes, commitment to change, available support system, and barriers to change. These conditions vary from person to person, which is why some smoking cessation programs work for one person and not another.

Medications

Before 1984, there were no medications to help smokers quit. In that year, a nicotine chewing gum (Nicorette) was approved by the U.S. Food and Drug Administration (FDA) as a prescription drug for smoking cessation. In 1996, it became available without prescription. Nicorette was the first of several medications used for nicotine replacement therapy, intended to gradually reduce nicotine dependence to prevent or reduce withdrawal symptoms. This approach, called tapering, is used in withdrawal of other addictive drugs. Studies indicate that people using these replacement therapies do not become addicted to them.

Nicotine gum comes in two strengths, 2 mg and 4 mg. Lozenges (Commit, Nicorette lozenge) are also available in the same doses. As the gum is chewed, nicotine is released and absorbed through the lining of the mouth. Over a 6- to 12-week period, the amount and strength of gum chewed can be decreased until the smoker is weaned away from dependence on nicotine. People trying to quit smoking are instructed to use the gum when they feel a craving. Products with **caffeine** may limit nicotine absorption and should be avoided in a window of time around the gum dose. Some people may not like the taste of the gum, and other common side effects include burning mouth and sore jaw. Pregnant or lactating women and persons with heart problems, diabetes, or **ulcers** should consult with a doctor before beginning any nicotine-replacement product.

Nicotine transdermal patches became available without prescription in 1996. They are marketed under several brand names, including Habitrol, Nicoderm, NicoDerm CQ, Prostep, and Nicotrol. All but Nicotrol are 24-hour patches; Nicotrol is a 16-hour patch designed to be removed at night. The patches are worn on the skin between the neck and the waist and provide a steady delivery of nicotine through the skin. Patches like Nicoderm come in varying strengths, and after several weeks, users can move down to a patch that delivers a lower dose. With the Nicotrol patch, a user simply ceases use after six weeks. Some people using the 24-hour patches experience sleep disturbances, and a few develop mild skin irritations, but generally side effects are few. Doctors recommend not smoking while using the patch.

As of 2014, two other nicotine delivery devices were available by prescription only. One was a nicotine nasal spray. It has the advantage of delivering nicotine rapidly, just as a cigarette does, but it delivers a much lower dose than a cigarette. Treatment with nasal spray usually lasts four to six weeks. Side effects

include cold-like symptoms (runny nose, sneezing, etc.). A nicotine inhaler was also available that delivers nicotine through the tissues of the mouth. A major advantage of the inhaler is that it provides an alternative to having a cigarette in one's hands while still delivering nicotine. It delivers less nicotine in cold weather (under 50°F). Recommendations for both the spray and the inhaler are that they be used at least hourly at first.

Prescription drugs outside of nicotine replacement therapy have been approved for the treatment of nicotine dependence. The first-approved drug was bupropion (Zyban), an antidepressant that acts to cut down withdrawal symptoms. This drug may be used in combination with a nicotine-replacement therapy and behavioral therapy.

A newer drug is varenicline (Chantix), which was developed to help people stop smoking. This drug acts directly on the proteins in the brain that recognize and bind nicotine. Interfering with their action not only stops the brain from sending the pleasurable message of nicotine but also reduces the feelings of nicotine withdrawal. Some studies indicate that this drug can double a person's chances of quitting smoking. Side effects of this drug can include **headache**, nausea, **vomiting**, sleep problems, gas, and changes in taste sensation.

Other drugs used in some smoking cessation programs include nortriptyline (Pamelor), a tricyclic antidepressant, and clonidine (Catapres), a high blood pressure medication. Side effects of these drugs include **dry mouth** and drowsiness. Both of these drugs are second-line treatments (used only when other treatments have shown no results) and are considered off-label uses (not approved by the FDA for this purpose).

Behavioral treatments

Behavioral treatments are used to help smokers learn to recognize and avoid specific situations that trigger desire for a cigarette. They also help the smoker learn to substitute other activities for smoking. Behavioral treatments are almost always combined with smoker education, and they usually involve forming a support network of other smokers who are trying to quit.

Behavioral treatments often take place in support groups either in person or online. They are most effective when combined with nicotine reduction therapy. Other supportive techniques include the use of rewards for achieving certain goals and contracts to clarify and reinforce the goals. Aversive techniques include asking the smoker to inhale the tobacco smoke deeply and repeatedly to the point of nausea, so that smoking is no longer associated with pleasurable sensations. Overall, quit rates are highest when behavior modification is combined with nicotine replacement therapy and tapering. Behavior modification once was conducted in person, but with the advent of a telephonic and virtual world on the Internet, behavioral approaches became available via mail, telephone, and the Web for greater access and flexibility. The U.S. Department of Health and Human Services sponsors a toll-free number for people who want to quit. This number served as the point of contact for smokers who wanted information and help.

Alternatives

Many alternative therapies have been tried to help smokers withdraw from nicotine. Hypnosis has proved helpful in some cases but has not been tested in controlled clinical trials. **Acupuncture**, relaxation techniques, restricted environmental stimulation therapy (REST, a combination of relaxation and hypnosis techniques), special **diets**, and herbal supplements have all been used to help people stop smoking. Of these alternative techniques, clinical studies of REST showed substantial promise in helping people stop smoking permanently.

Prognosis

Smoking is a major health risk associated with nicotine dependence, with approximately 50% of long-term smokers dying from smoking-related diseases, according to the FDA. It is the top cause of preventable death in the United States and kills an estimated 480,000 U.S. citizens each year—more than alcohol, illegal drug, homicide, **suicide**, car accidents, and HIV rates combined. Of those 480,000, about 40% die from cancer, 35% from **heart disease** and stroke, and 25% from lung disease. Most lung cancers, the leading cause of cancer death in the United States, are linked to smoking, and smoking is linked to about one-third of all cancer deaths. Smoking also causes such other lung problems as chronic **bronchitis** and **emphysema**, as well as worsening the symptoms of **asthma**. Other cancers associated with smoking include cancers of the mouth, esophagus, stomach, kidney, colon, and bladder. Smoking accounts for a large percentage of cardiovascular deaths and significantly increases the risk of heart disease, heart attack, stroke, and aneurysm. Women who smoke during pregnancy have more miscarriages, premature babies, and low–birth weight babies than nonsmokers. In addition, there is an increased risk that a child born to a mother who

WWW.BOOKBAZ.IR

smokes will die of **sudden infant death syndrome** (SIDS), making smoking an avoidable factor in this tragic occurrence. Secondhand smoke also endangers the health of nonsmokers in the smoker's family or workplace. Although most of these effects are not caused directly by nicotine, it is the dependence on nicotine that keeps people smoking.

Even though it is difficult for smokers to break their chemical and psychological dependence on nicotine, most of the negative health effects of smoking are reduced or reversed after quitting. Therefore, it is worth trying to quit smoking at any age, regardless of the length of time a person has had the habit.

Mental health problems

Persons with mental health problems, such as depression, anxiety, and schizophrenia, are two to three times more likely to smoke than persons without these conditions. However, smoking has also been associated with the risk of developing mental health problems, which has prompted some researchers to wonder whether smoking is a causal factor in mental illnesses or just prevalent due to effects of nicotine. However, one study suggested that tobacco smoke may have some implications in the development of mental illness. The study focused on the impact of secondhand smoke on individuals and found that nonsmokers were 1.5 times more likely to develop mental health problems if regularly exposed to secondhand smoke. A similar study focused on children found that children exposed to secondhand smoke were more likely to develop behavioral problems such as **attention deficit hyperactivity disorder (ADHD)**. Neither study is definitive of smoking's impact on mental health, and further research is needed, but along with the varied and severe physiological effects of smoking, there is risk of a negative psychological impact, as well.

Prevention

The best way to avoid nicotine dependence and withdrawal is to avoid the use of tobacco products. In September 2012, the FDA started requiring all cigarette manufacturers to display large, pictographic warning labels on cigarette packaging to deter consumers from purchasing cigarettes. The labels feature images focused on the negative effects of smoking, such as damaged lungs, oral cancer, children affected by secondhand smoke, and even a deceased person. The goal of the new labels was to both help current smokers quit smoking and to prevent others from starting smoking.

Night terrors

Definition

Night terrors are a sleep disorder characterized by **anxiety** episodes with extreme panic, often accompanied by screaming, flailing, fast breathing, and sweating that usually occur within a few hours after going to sleep.

Demographics

Night terrors occur most commonly in children between the ages of three and seven, especially boys ages five to seven; however, they can also occur in girls. After the age of seven they are not common at all. Night terrors may run in families. They can also

occur in adults, especially with adults who use alcohol or have emotional problems. Affected individuals usually suffer these episodes within a few hours after going to sleep. They appear to bolt up suddenly, and wake up screaming, sweating and panicked. The episode may last anywhere from five to 20 minutes. During this time, the individual is actually asleep, although the eyes may open. Quite often, nothing can be done to comfort the affected person. Very often, the person has no memory of the episode upon waking the next day.

KEY TERMS

Benzodiazepines—A class of drugs that suppresses Stage 4 of sleep.

REM sleep—Rapid Eye Movement phase of sleep, a mentally active period during which dreaming occurs.

Sleep disorder—Any disorder that keep a person from falling asleep or staying asleep.

Description

Night terrors are differentiated from nightmares in that they have been shown to occur during Stage 4 of sleep, or in REM sleep, while nightmares can occur anytime throughout the sleep cycle.

Causes and symptoms

Suffering from night terrors seems to run in families. Extreme tension or **stress** can increase the incidence of the episodes. In adults, the use of alcohol also contributes to an increased incidence of night terrors. Episodes sometimes occur after an accident involving **head injury**. Other factors thought to contribute to episodic night terrors, but not actually cause them, include:

- medications
- excessive tiredness at bedtime
- eating a heavy meal prior to bedtime drug abuse

Diagnosis

Night terrors are primarily diagnosed by observing the person suffering from an episode. The following symptoms are characteristic of a person suffering from a night terror:

- panic
- sweating
- gasping, moaning, crying, or screaming during sleep
- little or no recollection of the episode upon awakening

Treatment

In most cases, the individual will still be asleep as the night terror episode happens and will prove difficult to awaken. The goal should be to help the affected person go back into a calm state of sleep. The lights should be turned on, and soothing comments should be directed at the person, avoiding brusque gestures such as shaking the person or shouting to startle them out of the episode. Any form of stress should be avoided.

Individuals affected by night terrors should be evaluated by a physician if they are really severe and occur frequently. A physician can recommend the best treatment for the particular circumstances of the night terrors. In some severe cases, the physician may prescribe a benzodiazepine tranquilizer, such as Diazepam, known to suppress Stage 4 of sleep. The physician may also refer the affected person for further evaluation by a sleep disorder specialist. It should be noted that episodic night terrors in children are normal and do not suggest the presence of psychological problems. In adults, night terrors are more likely to be related to a significant stress–related or emotional problem.

Prognosis

In children, night terror episodes in children usually end by the age of 12.

Prevention

If a child seems to have a regular pattern of night terror episodes, he should be gently awakened about 15 minutes before the episode usually happens. The child should be kept awake and out of the bed for a short period of time and then allowed to return to bed.

Since **sleep deprivation** is a strong trigger for night terror episodes, children should not be allowed to become overtired. Having children take a nap during the day may be useful.

Adults affected by night terror episodes should avoid stress, the consumption of alcohol and stimulants before going to sleep.

Nipah

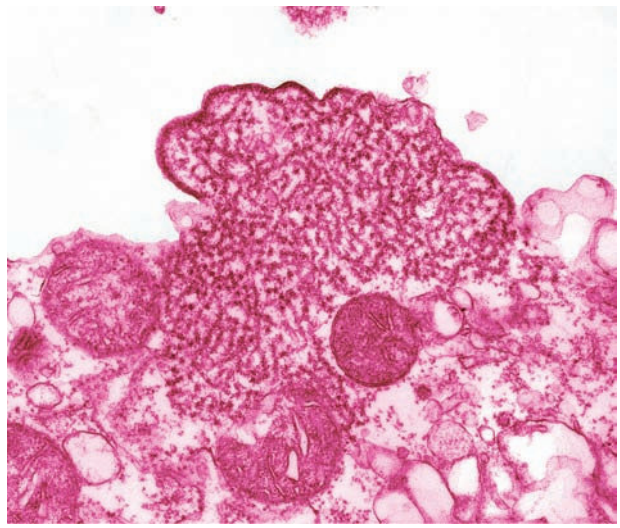
Definition

Nipah is a newly emerging, life-threatening disease caused by the nipah virus (NiV). It is a zoonosis—a disease that can be transmitted directly from animals to humans under natural conditions. Although outbreaks of nipah have been limited, they have been deadly. Furthermore, there is concern that the nipah virus could be engineered as a weapon of bioterror.

Description

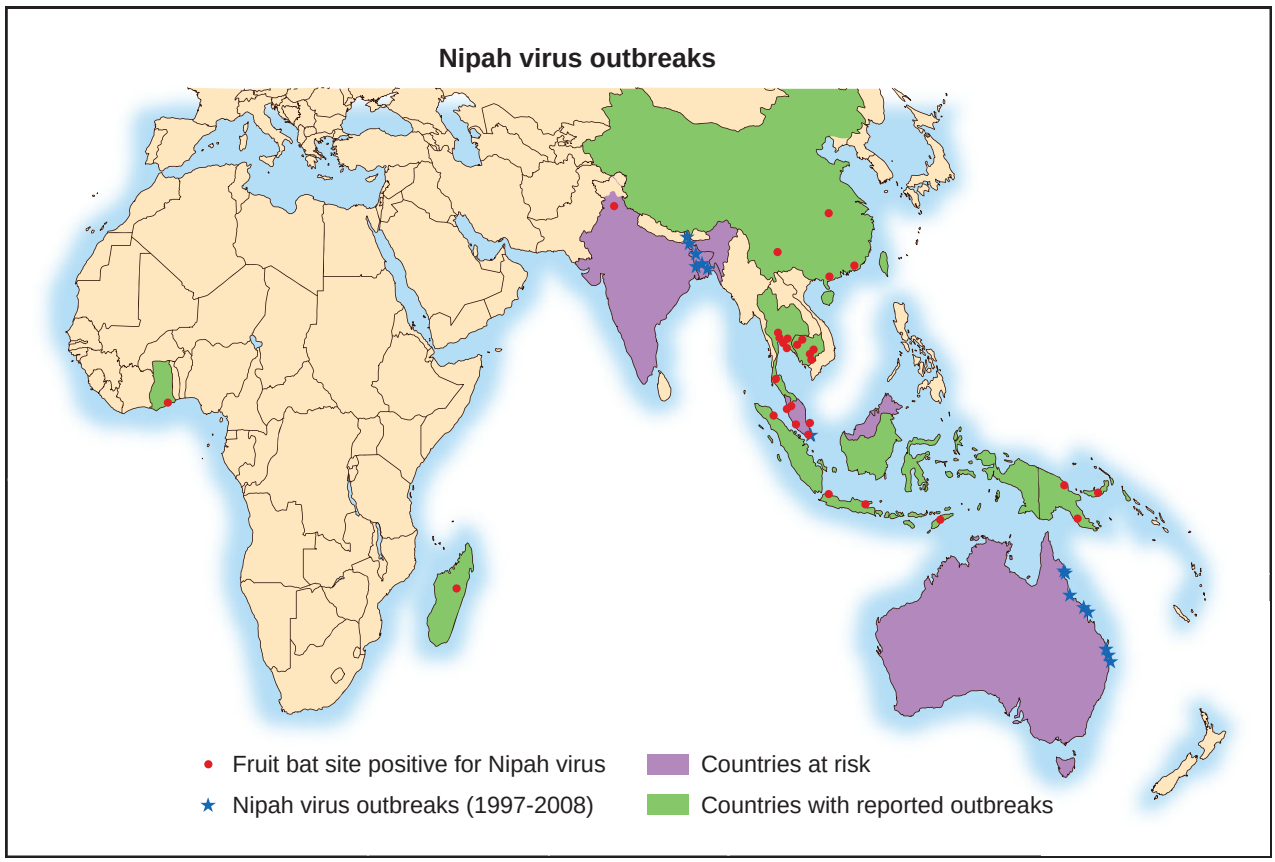
NiV is a member of the Paramyxoviridae family in the genus *Henipavirus*. The virus was first isolated and identified in 1999, in Malaysia and Singapore, during an outbreak of respiratory illness and encephalitis (a life-threatening inflammation of the brain) in pig farmers and others in close contact with pigs. The virus and the disease it caused were named for the village of Kampung Sungai Nipah in the Malaysian Peninsula, the center of the outbreak. NiV was shown to be closely related to the hendra virus, the only other identified member of the genus *Henipavirus*. Hendra virus had been first isolated in 1994 during an outbreak of respiratory and neurologic disease in humans and horses in Hendra, a suburb of Brisbane, Australia. Its host reservoir was identified as the fruit bat. However, as of 2013, only seven cases of human hendra virus infections had been confirmed. In contrast, in the 1998–1999 nipah outbreak, more than 250 people were sickened, and more than 40% of them died. Because of the relatedness of nipah and hendra viruses, the natural reservoir for NiV was quickly identified as a fruit bat of the genus *Pteropus* in the Pteropodidae family.

In the original nipah outbreak in Malaysia in 1998, pigs served as an intermediate host between bats and humans. Pigs at a massive pig farm first developed a loud, barking **cough** and began to behave strangely, with twitching and subsequent **muscle spasms**. Some pigs died. Soon the pig farm workers were also becoming ill and, in severe cases, fell into comas and died. *Pteropus* bats normally avoid people, but they live in nearby rainforests. Farmers on the pig farm had planted an orchard of mango trees near their pigpens, and the bats could not resist the juicy fruit. As they dined on the mangoes, their saliva, urine, and feces shed on the pigpens below. The pigs—and then their keepers—were infected with the virus from the bat waste. Eventually, more than one million pigs had to be slaughtered and their carcasses disposed of—at tremendous economic loss—to prevent the nipah outbreak from spreading.



Nipah virus. *(Copyright © BSIP / Custom Medical Stock Photo – All rights reserved.)*

During subsequent nipah outbreaks, there have been no intermediate hosts between bats and humans. NiV was identified again in the 2001 outbreak in Bangladesh; however, genetic sequencing of the virus revealed it to be a different strain than that identified in Malaysia in 1999. During the 2004 outbreak in Bangladesh, it was recognized that the affected humans had consumed date palm sap that had been contaminated by infected fruit bats. Date palms are tapped to harvest their sap, and the bats had been observed roosting in the trees and drinking the sap. Scientists at the National Institute of Allergy and Infectious Diseases' Rocky Mountain Laboratory have demonstrated that the virus can survive in artificial date palm sap for at least seven days. Another nipah outbreak was identified retrospectively in Siliguri, India. That outbreak included human-to-human transmission of the virus within hospital settings (nosocomial transmission).



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Risk factors

Thus far, the only known risk factors for nipah are close contact with NiV-infected pigs, contact with infected bats in India and Bangladesh, and consumption of raw date palm sap in those countries. However, regular documented reports of human-to-human transmission in India and Bangladesh mean that contact with NiV-infected people is also a risk factor. Human-to-human transmission most often occurs among family members and caregivers of infected patients.

Demographics

As of 2014, there had been more than 500 known cases of nipah, resulting in almost 300 deaths. Outbreaks of nipah have occurred in Malaysia and Singapore, in Bangladesh, and in India. In Malaysia, the outbreaks occurred among pig farmers and other people in close contact with pigs. In Bangladesh, outbreaks occurred among people consuming raw date palm sap. In the 1999 outbreak in Southeast Asia, there were more than 100 deaths among the almost 300 reported cases of nipah. No nipah outbreaks have been reported since then in either Malaysia or Singapore. However, there have been outbreaks in Bangladesh almost every year since 2001. In 2013, there were 24 reported cases resulting in 21 deaths. In the first six weeks of 2014, there were 18 reported cases and nine deaths. There also have been several outbreaks of nipah in India. Outbreaks of the closely related hendra virus have occurred among humans and horses in eastern Australia. However, the host reservoirs for both nipah and hendra viruses are fruit bats, often called flying foxes, of the genus *Pteropus*. These bats have a range that extends from Madagascar, throughout India and Southeast Asia, to Australia and some Pacific Islands. Thus, there is concern that nipah could spread to other human populations.

Causes and symptoms

Infection with NiV is caused by direct contact with infected bats or their saliva, urine, or feces, or close contact with infected pigs or humans. Both the nipah and hendra viruses enter into human cells by

WWW.BOOKBAZ.IR

KEY TERMS

Encephalitis—Life-threatening inflammation and swelling of the brain.

Endemic—Restricted or peculiar to a specific locale or region; especially a disease that is prevalent only in particular populations.

Enzyme-linked immunosorbent assay (ELISA)—An immunological test for detecting specific substances such as viruses and antibodies.

Hendra—A virus related to the nipah virus that infected horses and humans in Australia in 1994.

Henipavirus—A genus of viruses in the Paramyxoviridae family that thus far only includes the nipah and hendra viruses.

Immunoglobulin (Ig)—Antibodies against specific proteins or particles such as viruses; immunoglobulin M (IgM) is produced early in infection, followed by immunoglobulin G (IgG).

Nipah virus; NiV—The virus that causes nipah disease and nipah encephalitis.

Nosocomial—Occurring or acquired in a hospital, such as a hospital-acquired infection.

Outbreak—A sudden increase in the incidence of a disease.

Polymerase chain reaction (PCR)—A method used to directly detect and quantify viral genetic material in blood.

Pteropus—A genus of at least 60 tropical and subtropical bats, commonly called fruit bats or flying foxes, that are the largest bats in the world and include the reservoirs for nipah and hendra viruses.

Reservoir—An animal species, such as a bat, that harbors a virus, usually without symptoms of infection, and can transmit it to humans, either directly or via a vector.

Zoonosis—An animal disease, such as nipah, that can be transmitted to humans under natural conditions.

way of a protein receptor called Ephrin-B2 on the surfaces of cells in the central nervous system and lining blood vessels. Ephrin-B2 is essential for normal embryonic development of the human nervous system and blood vessel growth. Because many other mammals have this same receptor, the viruses can infect a broad range of species. The nipah virus specifically targets the lungs and the brain, causing respiratory illness and brain swelling or encephalitis.

NiV infections cause a range of symptoms in humans. Some infected people have no symptoms at all, whereas others develop acute respiratory illness and fatal encephalitis. Symptoms develop five to 14 days after exposure to the virus. Respiratory illness may occur early in the infection. **Fever** and **headache** last between three and 14 days. These may be followed by drowsiness, disorientation, and mental confusion that can progress to **coma** in 24–48 hours. About half of patients who experience severe neurological effects also had early respiratory symptoms.

Diagnosis

Examination

Nipah may be diagnosed from symptoms observed in a region where a known outbreak is occurring.

Tests

Nipah can be diagnosed with tests during both the acute and convalescent stages of the disease. In early stages, the virus may be isolated or its genetic material detected by real-time polymerase chain reaction (PCR) from swabs from the throat or nose or from blood, urine, or cerebrospinal fluid. Later on in the infection, immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies against the virus can be detected in the blood by enzyme-linked immunosorbent assays (ELISA). Sometimes the diagnosis can only be confirmed after death by tests on tissues from an **autopsy**.

Treatment

There is no treatment for nipah other than intensive supportive care.

Drugs

Results of studies using the antiviral drug ribavirin to treat nipah in humans have been inconclusive.

Prognosis

The nipah fatality rate may exceed 75%. In the 1998–1999 Malaysian outbreak, about 40% of patients hospitalized with severe neurologic disease died. There have also been reports of latent NiV infections that are subsequently reactivated, causing death months or even years after exposure to the virus. Survivors of nipah often suffer from permanent brain damage, including personality changes and persistent convulsions.

Prevention

Prevention of nipah includes avoiding exposure to bats and sick pigs in areas where the virus is endemic and refraining from consuming raw date palm sap. In Bangladesh, some workers are using tree skirts to keep bats away from the vats in which date palm sap is collected. **Infection control** practices and barrier nursing techniques are required to prevent nosocomial and person-to-person transmission. Awareness and surveillance are being increased in hopes of improving early detection of nipah in livestock and in communities and preventing future outbreaks.

Research on NiV and on the ecology of its bat host, including associations between NiV and bat reproductive cycles, is ongoing. Researchers are also continuing to investigate experimental treatments and vaccines. In 2012, they announced the development of a vaccine that can protect monkeys and cats from NiV, as well as protecting ferrets and horses from the hendra virus.

Nitrogen narcosis

Definition

Nitrogen narcosis is a condition that occurs in divers breathing compressed air. When divers go below depths of approximately 100 ft, increase in the partial pressure of nitrogen produces an altered mental state similar to alcohol intoxication.

Description

Nitrogen narcosis, commonly referred to as "rapture of the deep," typically becomes noticeable at 100 ft underwater and is incapacitating at 300 ft, causing

WWW.BOOKBAZ.IR

stupor, blindness, unconsciousness, and even death. Nitrogen narcosis is also called "the martini effect" because divers experience an effect comparable to that from one martini on an empty stomach for every 50 ft of depth beyond the initial 100 ft.

Causes and symptoms

Nitrogen narcosis is caused by gases in the body acting in a manner described by Dalton's law of partial pressures: The total pressure of a gas mixture is equal to the sum of the partial pressures of gases in the mixture. As the total gas pressure increases with increasing dive depth, the partial pressure of nitrogen increases and more nitrogen becomes dissolved in the blood. This high nitrogen concentration impairs the conduction of nerve impulses and mimics the effects of alcohol or **narcotics**.

Symptoms of nitrogen narcosis include: wooziness; giddiness; euphoria; disorientation; loss of balance; loss of manual dexterity; slowing of reaction time; fixation of ideas; and impairment of complex reasoning. These effects are exacerbated by cold, **stress**, and a rapid rate of compression.

Diagnosis

A diagnosis must be made on circumstantial evidence of atypical behavior, taking into consideration the depth of the dive and the rate of compression. Nitrogen narcosis may be differentiated from toxicity of oxygen, carbon monoxide, or carbon dioxide by the absence of such symptoms as **headache**, seizure, and bluish color of the lips and nail beds.

Treatment

The effects of nitrogen narcosis are totally reversed as the gas pressure decreases. They are typically gone by the time the diver returns to a water depth of 60 ft. Nitrogen narcosis has no hangover or lasting effects requiring further treatment. However, a doctor should be consulted whenever a diver has lost consciousness.

Prognosis

When a diver returns to a safe depth, the effects of nitrogen narcosis disappear completely. Some evidence exists that certain divers may become partially acclimated to the effects of nitrogen narcosis with frequency—the more often they dive, the less the increased nitrogen seems to affect them.

KEY TERMS

Compressed air—Air that is held under pressure in a tank to be breathed by underwater divers. A tank of compressed air is part of a diver's scuba (self-contained underwater breathing apparatus) gear.

Compression—An increase in pressure from the surrounding water that occurs with increasing diving depth.

Partial pressure—The pressure exerted by one of the gases in a mixture of gases. The partial pressure of the gas is proportional to its concentration in the mixture. The total pressure of the gas mixture is the sum of the partial pressures of the gases in it (Dalton's law of partial pressure) and as the total pressure increases, each partial pressure increases proportionally.

Prevention

Helium may be used as a substitute for nitrogen to dilute oxygen for deep water diving. It is colorless, odorless, tasteless, and chemically inert. However, it is more expensive than nitrogen and drains body heat from a diver. In diving with rapid compression, the helium-oxygen mixture may produce nausea, **dizziness**, and trembling, but these adverse reactions are less severe than nitrogen narcosis.

Nitrogen narcosis can be avoided by limiting the depth of dives. The risk of nitrogen narcosis may also be minimized by following safe diving practices, including proper equipment maintenance, low work effort, proper buoyancy, maintenance of visual cues, and focused thinking. In addition, no alcohol should be consumed within 24 hours of diving.

Nitroglycerin *see* **Antiangina drugs**
Nlein purpura *see* **Allergic purpura**
NMR *see* **Magnetic resonance imaging**
Nocardia asteroides infection *see* **Nocardiosis**

KEY TERMS

Abscess—A localized area of infection in a body tissue. Abscesses in the brain or skin are possible complications of nocardiosis.

Meningitis—An infection of the outer covering of the brain (meninges) that can be caused by either bacteria or a virus.

Nocardiosis

Definition

Nocardiosis is a serious infection caused by a fungus-like bacterium. The infection begins in the lungs and can spread to the brain.

Description

Nocardiosis is found throughout the world among people of all ages, although it is most common in older people and males. While people with poor immunity are vulnerable to this infection, it sometimes strikes individuals who have no history of other diseases. Nocardiosis is rare in **AIDS** patients. It is not transmitted by person-to-person contact.

Causes and symptoms

Nocardiosis is caused by a bacterium of the *Nocardia* species—usually *N. asteroides*, an organism that is normally found in the soil. The incubation period is not known, but is probably several weeks.

The bacteria can enter the human body when a person inhales contaminated dust. Less often, people can pick up the bacteria in contaminated puncture **wounds** or cuts.

The infection causes a **cough** similar to **pneumonia** or **tuberculosis**, producing thick, sometimes bloody, sputum. Other symptoms include chills, night sweats, chest **pain**, weakness, loss of appetite and weight loss. Nocardiosis does not, however, respond to short-term **antibiotics**.

Complications

In about one-third of patients, the infection spreads from the blood into the brain, causing brain abscesses. This complication can trigger a range of symptoms including severe **headache**, confusion, disorientation, **dizziness**, nausea and seizures, and problems in walking. If a **brain abscess** ruptures, it can lead to **meningitis**.

About a third of patients with nocardiosis also have abscesses in the skin or directly underneath the skin. They may also have lesions in other organs, such as the kidneys, liver, or bones.

Diagnosis

Nocardia is not easily identified from cultures of sputum or discharge. A doctor can diagnose the condition using special staining techniques and taking a thorough medical history. Lung biopsies or x rays also may be required. Up to 40% of the time, however, a diagnosis can't be made until an **autopsy** is done.

Treatment

Treatment of nocardiosis includes bed rest and high doses of medication for a period of 12 to 18 months, including sulfonamide drugs or a combination of trimethoprim-sulfamethoxazole (Bactrim, Septra). If the patient doesn't respond to these drugs, antibiotics such as ampicillin (Amcill, Principen) or erythromycin (E-Mycin, Eryc) may be tried.

The abscesses may need to be drained and dead tissue cut away. Other symptoms are treated as necessary.

Prognosis

Nocardiosis is a serious disease with a high mortality rate. If it has been diagnosed early and caught before spreading to the brain, the prognosis is better. Even with appropriate treatment, however, the death rate is still 50%. Once the infection reaches the brain, the death rate is above 80%. This outcome is most commonly seen in patients with a weakened immune system.

Non-nucleoside reverse transcriptase inhibitors

Definition

Non-nucleoside reverse transcriptase inhibitors (NRTI) are a type of drug that interferes with an enzyme that is key to the replication (reproduction) of the human **immunodeficiency** virus (HIV). The drug is designed to help suppress the growth of HIV, but does not eliminate it.

Purpose

This medication is used to treat patients with the HIV virus and **AIDS** in combination with one or more other AIDS drugs. Combining NRTIs with older drugs improves their ability to lower the levels of HIV in the bloodstream, and strengthens the immune system.

HIV becomes rapidly resistant to this class of drugs when they are used alone. However, in combination with older drugs, they can interfere with the virus's ability to become resistant because they attack the virus on several fronts. As the virus tries to evade one drug, another attacks. This combination can lower the level of HIV in the blood to undetectable levels.

KEY TERMS

Human immunodeficiency virus (HIV)—The virus that causes AIDS.

Precautions

Patients should not discontinue this drug without first consulting a physician—even if symptoms improve.

Description

Nucleoside analogues, the first class of HIV drugs to be developed, worked by incorporating themselves into the virus's DNA, making the DNA incomplete and therefore unable to create a new virus. Non-nucleoside inhibitors work at the same stage as nucleoside analogues, but act in a completely different way, preventing the conversion of RNA to DNA.

This class of drugs includes nevirapine (Viramune) and delavirdine (Rescriptor). It may take several weeks or months before the full benefits are apparent.

Depending on the drug prescribed, doses may start with a lower amount and be increased after a short period of time.

Risks

A mild skin rash is common; a severe skin rash can be a life-threatening reaction. Other possible side effects include **fever**, blistering skin, mouth sores, aching joints, eye inflammation, **headache**, nausea, and tiredness.

Because the drug passes into breast milk, **breastfeeding** mothers should avoid the drug, or not nurse until the treatment is completed.

Nongonococcal urethritis

Definition

Nongonococcal **urethritis** (NGU) is any inflammation of the urethra not due to **gonorrhea**. NGU is almost always contracted through sexual intercourse and is found far more often in men.

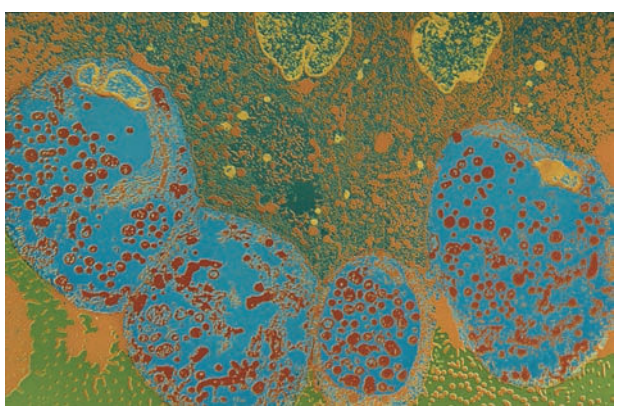
Description

Men between the ages of 15 and 30 who have multiple sex partners are most at risk for nongonococcal urethritis (NGU), which is believed to be the most common sexually transmitted disease in the United States.

Causes and symptoms

NGU is spread almost exclusively via sexual contact, and appears most often in men because a woman's urethra is less easily infected during sex. The infection is most often due to *Chlamydia trachomatis*, the organism that causes chlamydia. Those that aren't caused by *Chlamydia trachomatis* are usually due to another bacterium, *Ureaplasma urealyticum*. In 10–20% of NGU cases, the cause is unknown.

Symptoms appear within one to five weeks after infection, and include a slight clear discharge (the color of the discharge can vary from one patient to the next), and **itching** or burning during or after urination.



A microscopic image of non-specific urethritis. This sexually transmitted disease is usually caused by a bacterium of the genus *Chlamydia*. *(Custom Medical Stock Photo, Inc.)*

KEY TERMS

Chlamydia—One of the most common sexually transmitted diseases in the United States. It causes discharge, inflammation and burning during urination. About half of the cases of nongonococcal urethritis are due to chlamydia.

Gonorrhea—A sexually transmitted disease that affects the genital mucous membranes of men and women.

Urethra—The tube that carries urine from the bladder through the outside of the body.

However, some men never develop symptoms, and women almost never show signs of infection. However, it's possible that symptoms of burning or itching in or around the vagina may be due to NGU.

The disease is communicable from the time of first infection until the patient is cured. Past infection does not make a person immune.

Diagnosis

Nongonococcal urethritis is diagnosed by excluding other causes, since inflammation that is not caused by gonorrhea is classified as NGU. A microscopic and/or culture test of the discharge or urine can reveal the infection.

Since many people are infected with both NGU and **syphilis** at the same time, infected patients also should have a test for syphilis before treatment for NGU begins, and three months after treatment ends.

Treatment

Antibiotics such as tetracycline or azithromycin will cure NGU; both sexual partners should be treated at the same time.

Patients taking tetracycline should avoid milk or milk products and take the medication at least one hour before or two hours after meals. On the last day of treatment, a male should have a urine test to make sure the infection has cleared. If it has not, he should take a second course of therapy. Men should use a condom during treatment and for several months after treatment is completed.

WWW.BOOKBAZ.IR

If urine tests indicate the infection is gone but symptoms persist, the doctor will check for signs of prostate inflammation.

Prognosis

NGU is completely curable with proper antibiotic treatment. Untreated, NGU can lead to sterility in both men and women, inflammation of the mouth of the uterus, and infections of the woman's internal sexual organs. An infection during **pregnancy** may lead to **pneumonia** or eye infections in the newborn child. Untreated men may develop swelling of the testicles and an infected prostate gland.

Prevention

People can prevent the spread of NGU by:

- using a condom
- limiting the number of sex partners
- washing the genital area after sex
- if infected, avoid sexual contact; take antibiotics, notify all partners

Nonsteroidal anti-inflammatory drugs

Definition

Nonsteroidal anti-inflammatory drugs are medicines that relieve **pain**, swelling, stiffness, and inflammation.

Purpose

Nonsteroidal anti-inflammatory drugs (NSAIDs) are prescribed for a variety of painful conditions, including arthritis, **bursitis**, **tendinitis**, **gout**, menstrual cramps, sprains, strains, and other injuries. They are also given to control the pain of cancer and the side effects of **radiation therapy**.

A group of researchers associated with the Women's Health Initiative reported in 2003 that regular use of **aspirin**, ibuprofen, and other NSAIDs may help to lower a woman's risk of developing **breast cancer**. Further clinical trials are needed, however, to confirm the group's findings.

Description

Nonsteroidal anti-inflammatory drugs relieve pain, stiffness, swelling, and inflammation, but they do not cure the diseases or injuries responsible for these problems. Two drugs in this category, ibuprofen and naproxen, also reduce **fever**. Some nonsteroidal anti-inflammatory

drugs can be bought over the counter; others are available only with a prescription from a physician or dentist.

Among the drugs in this group are diclofenac (Voltaren), etodolac (Lodine), flurbiprofen (Ansaid), ibuprofen (Motrin, Advil, Rufen), ketorolac (Toradol), nabumetone (Relafen), naproxen (Naprosyn); naproxen **sodium** (Aleve, Anaprox, Naprelan); and oxaprozin (Daypro). They are sold as tablets, capsules, caplets, liquids, and rectal suppositories, and some are available in chewable, extended-release, or delayed-release forms.

A newer group of NSAIDs known as **COX-2 inhibitors** are being used successfully to treat patients with allergic reactions to the older NSAIDs. Their name comes from the fact that they block an enzyme known as cyclooxygenase-2, or COX-2, which is involved in the inflammation pathway. The COX-2 inhibitors are also less likely to affect the patient's digestive tract. They include such drugs as celecoxib (Celebrex), rofecoxib (Vioxx), etoricoxib (Arcoxia), and valdecoxib (Bextra). With regard to cancer treatment, some studies indicate that the use of COX-2 inhibitors may postpone the need to prescribe narcotic medications for severe pain.

Recommended dosage

Recommended doses vary, depending on the patient, the type of nonsteroidal anti-inflammatory drug prescribed, the condition for which the drug is prescribed, and the form in which it is used. Always take nonsteroidal anti-inflammatory drugs exactly as directed. If using non-prescription (over-the-counter) types, follow the directions on the package label. For prescription types, check with the physician who prescribed the medicine or the pharmacist who filled the prescription. Never take larger or more frequent doses, and do not take the drug for longer than directed. Patients who take nonsteroidal anti-inflammatory drugs for severe arthritis must take them regularly over a long time. Several weeks may be needed to feel the results, so it is important to keep taking the medicine, even if it does not seem to be working at first.

When taking nonsteroidal anti-inflammatory drugs in tablet, capsule, or caplet form, always take them with a full, 8-ounce glass of water or milk. Taking these drugs with food or an antacid will help prevent stomach irritation.

Precautions

Nonsteroidal anti-inflammatory drugs can cause a number of side effects, some of which may be very serious. These side effects are more likely when the drugs are taken in large doses or for a long time, or when two or more nonsteroidal anti-inflammatory drugs are taken together. Healthcare professionals can help patients weigh the risks or benefits of taking these medicines for long periods.

Do not take **acetaminophen**, aspirin, or other salicylates along with other nonsteroidal anti-inflammatory drugs for more than a few days unless directed to do so by a physician. Do not take ketorolac (Toradol) while taking other nonsteroidal anti-inflammatory drugs unless directed to do so by a physician.

Because older people are more sensitive than younger adults to nonsteroidal anti-inflammatory drugs, they may be more likely to have side effects. Some side effects, such as stomach problems, may also be more serious in older people.

Serious side effects are especially likely with one nonsteroidal anti-inflammatory drug, phenylbutazone. Patients age 40 and over are especially at risk of side effects from this drug, and the likelihood of serious side effects increases with age. Because of these potential problems, it is especially important to check with a physician before taking this medicine. Never take it for anything other than the condition for which it was prescribed, and never share it—or any other prescription drug—with another person.

Some nonsteroidal anti-inflammatory drugs can increase the chance of bleeding after surgery (including dental surgery), so anyone who is taking the drugs should alert the physician or dentist before surgery. Avoiding the medicine or switching to another type in the days prior to surgery may be necessary.

Some people feel drowsy, dizzy, confused, lightheaded, or less alert when using these drugs. Blurred vision or other vision problems also are possible side effects. For these reasons, anyone who takes these drugs should not drive, use machines or do anything else that might be dangerous until they have found out how the drugs affect them.

Nonsteroidal anti-inflammatory drugs make some people more sensitive to sunlight. Even brief exposure to sunlight can cause severe **sunburn**, **rashes**, redness, **itching**, blisters, or discoloration. Vision changes also may occur. To reduce the chance of these problems, avoid direct sunlight, especially from mid-morning to mid-afternoon; wear protective clothing, a hat, and sunglasses; and use a sunscreen with a skin protection factor (SPF) rating of at least 15. Do not use sunlamps, **tanning** booths or tanning beds while taking these drugs.

WWW.BOOKBAZ.IR

Special conditions

People with certain medical conditions and people who are taking some other medicines can have problems if they take nonsteroidal anti-inflammatory drugs. Before taking these drugs, be sure to let the physician know about any of these conditions:

ALLERGIES. Let the physician know about any **allergies** to foods, dyes, preservatives, or other substances. Anyone who has had reactions to nonsteroidal anti-inflammatory drugs in the past should also check with a physician before taking them again.

PREGNANCY. Women who are pregnant or who plan to become pregnant should check with their physicians before taking these medicines. Whether nonsteroidal anti-inflammatory drugs cause **birth defects** in people is unknown, but some do cause birth defects in laboratory animals. If taken late in **pregnancy**, these drugs may prolong pregnancy, lengthen labor time, cause problems during delivery, or affect the heart or blood flow of the fetus.

BREASTFEEDING. Some nonsteroidal anti-inflammatory drugs pass into breast milk. Women who are **breastfeeding** should check with their physicians before taking these drugs.

OTHER MEDICAL CONDITIONS. A number of medical conditions may influence the effects of nonsteroidal anti-inflammatory drugs. Anyone who has any of the conditions listed here should tell his or her physician about the condition before taking nonsteroidal anti-inflammatory drugs.

- stomach or intestinal problems, such as colitis or Crohn's disease
- liver disease
- current or past kidney disease; current or past kidney stones
- heart disease
- high blood pressure
- blood disorders, such as anemia, low platelet count, low white blood cell count
- bleeding problems
- diabetes mellitus
- hemorrhoids, rectal bleeding, or rectal irritation
- asthma
- Parkinson's disease
- epilepsy
- systemic lupus erythematosus
- diseases of the blood vessels, such as polymyalgia rheumatica and temporal arteritis
- fluid retention
- alcohol abuse
- mental illness

People who have sores or white spots in the mouth should tell the physician about them before starting to take nonsteroidal anti-inflammatory drugs. Sores or white spots that appear while taking the drug can be a sign of serious side effects.

SPECIAL DIETS. Some nonsteroidal anti-inflammatory drugs contain sugar or sodium, so anyone on a low-sugar or low-sodium diet should be sure to tell his or her physician.

SMOKING. People who smoke cigarettes may be more likely to have unwanted side effects from this medicine.

USE OF CERTAIN MEDICINES. Taking nonsteroidal anti-inflammatory drugs with certain other drugs may affect the way the drugs work or increase the risk of unwanted side effects.

Side effects

The most common side effects are stomach pain or cramps, nausea, **vomiting**, **indigestion**, **diarrhea**, **heartburn**, **headache**, **dizziness** or lightheadedness, and drowsiness. As the patient's body adjusts to the medicine, these symptoms usually disappear. If they do not, check with the physician who prescribed the medicine.

Serious side effects are rare, but do sometimes occur. If any of the following side effects occur, stop taking the medicine and get emergency medical care immediately:

- swelling or puffiness of the face
- swelling of the hands, feet, or lower legs
- rapid weight gain
- fainting
- breathing problems
- fast or irregular heartbeat
- tightness in the chest

Other side effects do not require emergency medical care, but should receive medical attention. If any of the following side effects occur, stop taking the medicine and call the physician who prescribed the medicine as soon as possible:

- severe pain, cramps, or burning in the stomach or abdomen
- convulsions
- fever
- severe nausea, heartburn, or indigestion
- white spots or sores in the mouth or on the lips

KEY TERMS

Anemia—A lack of hemoglobin—the compound in blood that carries oxygen from the lungs throughout the body and brings waste carbon dioxide from the cells to the lungs, where it is released.

Bursitis—Inflammation of the tissue around a joint.

Colitis—Inflammation of the colon (large bowel)

COX-2 inhibitors—A class of newer nonsteroidal anti-inflammatory drugs (NSAIDs) that are less likely to cause side effects in the digestive tract. COX-2 inhibitors work by inhibiting the production of cyclooxygenase-2, an enzyme involved in inflammation.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Salicylates—A group of drugs that includes aspirin and related compounds. Salicylates are used to relieve pain, reduce inflammation, and lower fever.

Tendinitis—Inflammation of a tendon, which is a tough band of tissue that connects muscle to bone.

- rashes or red spots on the skin
- any unusual bleeding, including nosebleeds, spitting up or vomiting blood or dark material
- black, tarry stool
- chest pain
- unusual bruising
- severe headaches

A number of less common, temporary side effects are also possible. They usually do not need medical attention and will disappear once the body adjusts to the medicine. If they continue or interfere with normal activity, check with the physician. Among these side effects are:

- gas, bloating, or constipation
- bitter taste or other taste changes
- sweating
- restlessness, irritability, anxiety
- trembling or twitching

Some patients who have had problems with side effects from NSAIDs may benefit from **acupuncture** as an adjunctive treatment in **pain management**. A recent study done in New York found that older patients with lower back pain related to cancer reported that their pain was relieved by acupuncture with fewer side effects than those caused by NSAIDs.

Interactions

Nonsteroidal anti-inflammatory drugs may interact with a variety of other medicines. When this happens, the effects of the drugs may change, and the risk of side effects may be greater. Anyone who takes these drugs should let the physician know all other medicines he or she is taking. Among the drugs that may interact with nonsteroidal anti-inflammatory drugs are:

- blood thinning drugs, such as warfarin (Coumadin)
- other nonsteroidal anti-inflammatory drugs
- heparin
- tetracyclines
- cyclosprorine
- digitalis drugs
- lithium
- phenytoin (Dilantin)
- zidovudine (AZT, Retrovir).

NSAIDs may also interact with certain herbal preparations sold as dietary supplements. Among the herbs known to interact with NSAIDs are bearberry (*Arctostaphylos uva-ursi*), feverfew (*Tanacetum parthenium*), evening primrose (*Oenothera biennis*), and gossypol, a pigment obtained from cottonseed oil and used as a male contraceptive. In most cases, the herb increases the tendency of NSAIDs to irritate the digestive tract. It is just as important for patients to inform their doctor of herbal remedies that they take on a regular basis as it is to give the doctor a list of their other prescription medications.

Noroviruses

Definition

Noroviruses are a group of related, single-stranded RNA (ribonucleic acid) viruses that cause infection resulting in acute **gastroenteritis** in humans. Gastroenteritis, also commonly called stomach flu, involves an inflammation of the gastrointestinal tract, which results in **diarrhea**, abdominal **pain**, and **vomiting**. The infection caused by noroviruses is very highly contagious, being commonly spread through water or food that has been contaminated with fecal matter; or through contact with an infected person. Norovirus infections occur frequently in closed, and often-times crowded, environments where the viruses can quickly spread. Such places include as hospitals and medical facilities, schools, nursing/retirement homes and day-care facilities, and cruise ships.

Demographics

Anyone can become infected with a norovirus. During norovirus outbreaks there are high rates of infection among people of all ages. There are a large number of genetically distinct strains of noroviruses. Immunity appears to be specific for the norovirus strain and lasts for only a few months. Therefore, norovirus infection can recur throughout a person's lifetime. Because of genetic (inherited) differences among humans, some people appear to be more susceptible to norovirus infection and may suffer more severe illness. People with type O blood are at the highest risk for severe infection.

Description

Norovirus infection is caused by a variety of viruses. All such viruses cause acute gastroenteritis, an inflammation of the stomach and intestines. The illness is highly contagious, and usually requires professional medical care to treat the most serious of the symptoms, which often times included **dehydration**, bloody stool, abdominal pain, and vomiting. Noroviruses are difficult to eliminate in the environment because they can withstand very high and low temperatures, along with being able to resist most disinfectants.

Noroviral infection

Noroviruses are a major cause of viral gastroenteritis—an inflammation of the linings of the stomach and small and large intestines that causes vomiting and diarrhea. Viruses are responsible for 30–40% of all cases of infectious diarrhea, and viral gastroenteritis is the second most common illness in the United States, exceeded only by the **common cold**.

Infected individuals are contagious from the first onset of symptoms until at least three days after full recovery. Some people may remain contagious for as long as two weeks after recovery.

Gastroenteritis

Gastroenteritis often is referred to as the stomach flu even though the flu is a respiratory illness caused by an **influenza** virus. Other common names for viral gastroenteritis include:

- food poisoning
- winter-vomiting disease
- non-bacterial gastroenteritis
- calicivirus infection.

The U.S. Centers for Disease Control and Prevention (CDC) estimate, in 2010, that noroviruses are responsible for some 21 million cases of acute gastroenteritis in the United States every year. Epidemiologists estimate that about 50,000 Americans are hospitalized annually and about 400 people die each year because of norovirus infection. However, the CDC reported in 2006 that many reports of acute gastroenteritis go unreported. Consequently, the U.S. health organization suggests that up to 300,000 hospitalizations occur annually and about 5,000 deaths occur each year, all due to noroviruses. In developing countries, noroviruses are a major cause of human illness. The CDC estimate that about 900,000 visits to clinics and other medical facilities by children in developed countries of the world result in about 64,000 hospitalizations. Even worse, about 200,000 children under the age of five years die from noroviruses each year in developing countries of the world.

Gastroenteritis caused by infection with a norovirus is rarely a serious illness. Typically an infected person suddenly feels very ill and may vomit many times in a single day. The symptoms, although quite unpleasant, usually last only 24 to 60 hours.

Transmission

Noroviruses are ubiquitous in the environment. They are highly contagious and are considered to be among the most infectious of viruses. The reasons for this include:

- Only a small number of viral particles—as few as 10—are required for infection.
- Although noroviruses cannot reproduce outside of their human hosts, they can remain viable for weeks or even months on objects and surfaces.
- Human immunity to norovirus is short-lived and strain-specific.

Noroviruses are transmitted among people by a fecal-oral route, either by ingestion of food or water contaminated with feces or by contact with the vomit or feces of an infected person. Norovirus infection can occur by:

- consuming contaminated food or liquids
- hand contact with contaminated objects or surfaces, followed by hand contact with the mouth
- contact with an infected person, including caring for the sick person or sharing food or utensils
- aerosolized vomit that is swallowed or that contaminates surfaces.

Environmental contamination or contact with infected clothing or linen also may be a source of transmission. Although evidence is not available that norovirus infection can occur via the respiratory system, the sudden and violent vomiting of noroviral gastroenteritis can lead to contamination of the surroundings and of public areas. Particles laden with virus can be suspended in the air and swallowed.

FOODBORNE TRANSMISSION. Noroviruses account for at least 50% of food-related outbreaks of gastroenteritis. A European study, published in 2010, showed that 21% of all norovirus outbreaks are caused by foodborne transmission. In addition, 25% of the outbreaks were initially reported to be "food handler-associated." This was later found to be caused from contamination of the food source. In addition, restaurant or catered foods are common sources of norovirus transmission, with subsequent infection of household members. The majority of norovirus outbreaks occur via contamination by a food handler immediately before the food is consumed.

Foods that frequently are associated with norovirus outbreaks include:

- foods that are eaten without further cooking, including sandwiches, salads, and bakery products
- liquids such as salad dressing or cake icing in which the virus becomes evenly distributed
- food that is contaminated at its source, including oysters and clams from contaminated waters and raspberries irrigated with sewage-contaminated water
- food that becomes contaminated before distribution, including salads and frozen fruit.
- Shellfish, including oysters and clams, concentrate norovirus from contaminated water in their tissues. Steaming shellfish may not completely inactivate the virus.

WATERBORNE TRANSMISSION. There is widespread norovirus contamination of rivers and seas, often with more than one strain of the virus. Waterborne outbreaks of norovirus have been associated with:

- sewage-contaminated wells
- contaminated municipal water systems

WWW.BOOKBAZ.IR

- stream and lake water
- swimming pools and spas
- commercial ice.

Outbreaks

Norovirus infection can spread rapidly through daycare centers, schools, prisons, hospitals, nursing homes, camps, and other confined spaces. Norovirus is responsible for about 40% of group- or institution-related outbreaks of diarrhea. Outbreaks usually peak during the winter months.

In 2008, it was reported that outbreaks of the norovirus occurred on several university campuses in California, Michigan, and Wisconsin. The CDC, along with state and local health departments, found that approximately 1,000 cases of illness resulted from these outbreaks, including 10 hospitalizations. In addition, one college campus was closed temporarily due to an outbreak.

Cruise ships have become notorious for norovirus outbreaks among passengers and staff. Cruise ships and naval vessels are at increased risk for contamination when docking in regions that lack adequate sanitation and where contaminated food or water may be brought onboard. Close living quarters and the arrival of new, susceptible passengers every one to two weeks exacerbate outbreaks on cruise ships. Norovirus outbreaks have been reported to continue through more than 12 successive cruises on a single ship.

Noroviruses are relatively rare on cruise ships but they do happen. In 2006, the CDC reported that 34 cases of norovirus were reported, while 27 were reported in 2007, 15 in 2008, 13 in 2009, and 4 in 2013—all from cruises originating from U.S. ports. In 2010, for instance, the Celebrity Cruises company had about 15% of its passengers come down with norovirus-like symptoms on its cruise ship that departed from Charleston, South Carolina, on February 15, 2010. A year before the incident, a paper published in the medical journal *Clinical Infectious Diseases* found that a large number of norovirus outbreaks on cruise ships were the result of dirty public restroom facilities. However, in 2010, the CDC reported that the trend was down for contracting a norovirus on a cruise ship sailing from a U.S. port. Less than 1% of passengers become infected with norovirus each year. Cruise Lines International Association (CLIA) reports that 1 in 15 people contract norovirus on land, whereas, only 1 in 12,000 contract it on a cruise ship. As reported by the CDC, the outbreaks on cruise ships during the 2000s were on the decline.

Generally, outbreaks of norovirus appear on the increase. Near the end of the 2000s, the CDC reported that norovirus outbreaks were increasing in many closed, crowded facilities across the country.

Risk factors

Humans are at increased risk from contracting noroviruses if they:

- travel frequently on cruise ships or stay at lodging establishments where many people are living in close surroundings
- live with children that attend school or day care
- have a weakened immune system
- live in nursing homes, retirement centers, or other such facilities.

Causes and symptoms

Norovirus strains

Noroviruses lack outer envelopes and their genetic material is carried as single-stranded RNA rather than DNA (deoxyribonucleic acid). Although noroviruses are not new, the extent of norovirus infection was not recognized until the 1990s. This has led to increased research on noroviruses and more monitoring of outbreaks.

Until 2004 noroviruses were commonly referred to as:

- Norwalk virus
- Norwalk-like viruses (NLVs)
- caliciviruses
- small, round-structured viruses (SRSVs).

Noroviruses are named after the original strain—the Norwalk virus—that caused an outbreak of gastroenteritis in a Norwalk, Ohio, school in 1968. The virus was identified in 1972. Since then many related viruses have been identified. In 2004, these viruses were grouped together in the genus *Norovirus* within the Caliciviridae family of viruses. Eight to 10 distinct genogroups of norovirus have been found in various parts of the world. There are five common genogroups and, of those, three (GI, GII, and GIV) affect humans. Each of these groups can be further differentiated into at least 20 genetic clusters. Evidence suggests that noroviruses in different genetic clusters can recombine to form new, genetically distinct noroviruses. As of 2014, GII strains, especially GII4, are the most prevalent, and have caused the most norovirus outbreaks since 2002. However the most common method of identifying noroviruses—the reverse transcription-polymerase

chain reaction (RT-PCR)—may not always identify GII genetic clusters correctly.

The increased number of norovirus outbreaks in European countries in the early 2000s—occurring in the spring and summer rather than in winter—were found to be associated with the emergence of a new variant of the GII4 strain. Increased international outbreaks in 2003 and 2004 also were caused by a GII4-related norovirus that was found to mutate rapidly. Mutations in the viral capsid—the virus' outer protective layer—were used to determine the predominant routes of norovirus transmission.

Then, in the first quarter of 2010, 334 cases of norovirus were reported at 65 different locations within the United Kingdom, Norway, France, Sweden, and Denmark. All of the cases were associated with the eating of raw oysters. The International Society of Infectious Diseases reports that the Rapid Alert System for Food and Feed database contained 19 reports of norovirus in oysters between March 2006 and March 2010—all within the European Union.

Symptoms

Symptoms of norovirus infection usually appear within 24–48 hours after exposure, with a median incubation period during outbreaks of 33–36 hours. However symptoms can occur as early as 12 hours or less after exposure.

Typical symptoms of norovirus infection are:

- nausea
- vomiting
- fever
- malaise (general feeling of sickness)
- watery or loose diarrhea without blood
- abdominal cramping and pain
- bloody stool
- dehydration
- weight loss.

Among children, vomiting is the predominant symptom, whereas diarrhea is more common in adults. Vomiting can be frequent and violent and may occur without warning.

Additional symptoms of norovirus infection may include:

- low-grade fever
- chills
- headache
- muscle aches
- fatigue.

Dehydration is the major risk from gastroenteritis caused by norovirus, particularly among infants, young children, the elderly, and those with underlying health conditions. Symptoms of dehydration include:

- dry mouth
- increased or excessive thirst
- low urine output
- nausea
- dizziness or faintness
- sunken eyes
- sunken fontanelle—the soft spot on an infant's head
- confusion.

As many as 30–50% of norovirus infections do not produce symptoms. It is not known whether individuals with asymptomatic infections can transmit the virus.

Diagnosis

Identifying noroviruses

Viral gastroenteritis usually is diagnosed on the basis of the symptoms. Many types of viruses cause gastroenteritis. Rotoviruses are a leading cause of gastroenteritis in children who then transmit the virus to adults. In addition to noroviruses, viral gastroenteritis in humans can be caused by another genus of viruses within the Caliciviridae family. Formerly known as the Sapporo-like virus, or classic or typical calicivirus, these now are grouped in the genus *Sapovirus*. Other genera in the Caliciviridae family are not pathogenic in humans. Some bacteria and parasites also cause illnesses that are similar to norovirus infection.

The cloning and sequencing of noroviruses in the early 1990s made it easier to identify norovirus outbreaks. RT-PCR is the most commonly used method for identifying norovirus. With this technique the virus' RNA is used as the template for transcribing the corresponding DNA using the enzyme reverse transcriptase. The DNA is amplified into many copies using the polymerase chain reaction. Many state **public health** laboratories use this method to detect norovirus in vomit and stools. The best identification usually comes from stool samples taken within 48–72 hours after the onset of symptoms; however norovirus can be detected in stool samples taken five days after the onset of symptoms and sometimes even in samples taken up to two weeks after recovery.

Norovirus from fecal samples can be visualized using electron microscopy. With immune electron microscopy (IEM), antibodies against norovirus are collected from blood serum and used to trap and

WWW.BOOKBAZ.IR

visualize the virus from fecal samples. However these methods require high concentrations of norovirus in the stool, as well as a fourfold increase in norovirus-specific antibodies in blood samples taken during the acute or recovery phases of gastroenteritis.

Enzyme-linked immunosorbent assays may be used to detect noroviruses in fecal samples. In these assays noroviral-specific antibodies bound to the virus are detected by the reaction of an enzyme that is attached to the antibody. Nucleic acid probes that hybridize with noroviral RNA also can be used for virus detection in feces.

A Japanese chemical company was producing a reagent kit that can be used to detect norovirus in two hours rather than the 12–24 hours needed for conventional detection. Other simpler methods for rapidly identifying norovirus are under development. As of 2014, further research is continuing on commercial devices for detecting norovirsuses. For example, scientists at the Department of Infectious Diseases, Osaka Prefectural Institute of Public Health (Osaka, Japan) are developing modified reagent kits for norovirus genogroups I and II. They reported their advancement in the *Journal of Medical Virology* (December 2009).

Investigating outbreaks

Epidemiological studies often involve sequencing the norovirus RNA. This can help to determine whether outbreaks in different geographical locations are connected to each other and can help trace the source of the norovirus to contaminated food or water. CaliciNet is a database that stores the RNA sequences of all norovirus strains that cause gastroenteritis in the United States.

Criteria that are sometimes used to determine whether an outbreak of gastroenteritis is caused by a norovirus include:

- a mean incubation period of 24–48 hours
- a mean duration time for illness of 12–60 hours
- vomiting in more than 50% of patients
- failure to find a bacterial cause for the illness.

During investigations of norovirus outbreaks, food handlers may be asked to provide a stool sample and possibly a blood sample. Food rarely is tested for norovirus since each type of food requires a specific assay. However, tests are used to detect the virus in shellfish. When large amounts—1–26 gallons (5–100 liters)—of water are processed through specially designed filters, the norovirus can be concentrated and assayed by RT-PCR.

Treatment

Gastroenteritis caused by noroviruses usually resolves itself without treatment within a very few days. As of 2014, medications or vaccines are not available that are effective against the norovirus. Viruses are not affected by **antibiotics** and antidiarrheal medications may prolong the infection.

Norovirus infections should be treated by:

- drinking plenty of fluids, such as water and juice, to prevent dehydration caused by vomiting and diarrhea
- intravenous fluids if severe nausea prevents drinking, particularly in small children
- drinking oral rehydration fluids (ORFs) to prevent dehydration and to replace electrolytes (salt and minerals) and glucose
- avoiding alcohol and caffeine which can increase urination.

Commercially available ORFs include Naturalyte, Pedialyte, Infalyte, and Rehydralyte.

Juice, soda, and water do not replace lost electrolytes; nor do sports drinks replace nutrients and **minerals** lost through vomiting and diarrhea. In fact, drinks containing sugar may make diarrhea worse. Those taking **diuretics** should ask their healthcare provider whether to stop taking the medication during acute diarrhea.

Since the risk of dehydration is higher for infants and young children, the number of wet diapers per day should be closely monitored. Severely dehydrated children may receive rapid **intravenous rehydration** in a hospital or emergency-room setting.

A healthcare provider should be consulted if:

- symptoms of dehydration appear
- diarrhea persists for longer than a few days
- there is blood in the stool.

Alternatives

An infusion of meadowsweet (*Filipendula ulmaria*) may reduce nausea. Once the symptoms are reduced, slippery elm (*Ulmus fulva*) may calm the digestive system. Castor oil packs placed on the abdomen can reduce inflammation and discomfort.

Homeopathic remedies for gastroenteritis include *Arsenicum album*, **ipecac**, and *Nux vomica*. Chinese patent herbal remedies include Po Chai and Pill Curing.

During recovery from viral gastroenteritis, live cultures of *Lactobacillus acidophilus*, found in live-culture

yogurt or as powder or capsules, may be useful for restoring the native flora of the digestive tract.

Prognosis

Norovirus infection is usually followed by complete recovery. Any long-term health effects are not known. Infected persons do not become long-term carriers of the virus. However, in some cases dehydration can become a very serious possible consequence of noroviral infection and can be fatal, particularly among young children, older people, and anyone with debilitating medical conditions or impaired immune systems.

Prevention

Noroviruses are difficult to destroy. They can survive freezing as well as temperatures as high as 140°F (60°C). Noroviruses can survive chlorine levels as high as 10 parts per million (ppm), far higher than the levels present in most public water systems. A 2004 study from the Netherlands found that inactivation of norovirus with 70% ethanol was inefficient and that **sodium** hypochlorite solutions were effective only at concentrations above 300 ppm.

The best prevention against noroviral infection is frequent, thorough hand washing with soap and water. All soaped hand surfaces should be rubbed vigorously for at least 10 seconds. The hands should be thoroughly rinsed under a stream of water. In particular hands always should be washed before handling food and after using the toilet or changing diapers.

Other important measures for preventing norovirus infection include:

- proper handling of cold foods
- careful washing of fruits and vegetables
- steaming oysters before eating, although even this may be insufficient for destroying norovirus
- taking particular care when handing the diapers of children with diarrhea
- properly disposing of sewage and diapers
- excluding sick infants and children from food preparation areas.

To prevent further transmission of norovirus:

- All surfaces exposed to vomit or otherwise contaminated should be immediately cleaned and disinfected with a solution of between 5 to 10% bleach, followed by rinsing.
- Contaminated clothing and linens should be removed immediately and washed with hot water and detergent on the maximum machine cycle and with a minimum of handling, followed by machine drying.
- Vomit and feces should be discarded or flushed immediately and the toilet area should be kept clean.
- Exposed or contaminated food should be discarded.
- Masks may be worn while cleaning areas that have been badly contaminated with vomit or feces, such as in hospitals or nursing homes.
- Stay home and do not go to work or school in order to prevent further passing on of the virus.

Scientific studies have found that detergent-based cleaning with a cloth consistently fails to eliminate norovirus contamination. With fecal contamination, detergent-based cleaning, followed by cleaning with a combination hypochlorite/detergent formula containing 5,000 ppm of available chlorine significantly reduced contamination. However, norovirus still could be detected on as much as 28% of the surfaces. When this procedure failed to eliminate contamination, the virus was transmitted to the cleaner's hands. Contaminated fingers consistently transferred norovirus to up to seven different surfaces including doorknobs and telephones. However the contamination was diluted during secondary transmission and treatment with the combined bleach/detergent eliminated the virus without prior cleaning.

KEY TERMS

Antibody—A blood protein produced in response to foreign material such as a virus; the antibody attaches to the virus and destroys it.

Calicivirus—A member of the Caliciviridae family of viruses that includes noroviruses.

Capsid—The outer protein coat of a virus.

Gastroenteritis—An inflammation of the lining of the stomach and intestines, usually caused by a viral or bacterial infection.

Genetic cluster—A group of viral strains with very similar, yet distinct, nucleic acid sequences.

Genogroup—Related viruses within a genus; may be further subdivided into genetic clusters.

Reverse transcription-polymerase chain reaction (RT-PCR)—A method of polymerase-chain-reaction amplification of nucleic acid sequences that uses RNA as the template for transcribing the corresponding DNA using reverse transcriptase.

WWW.BOOKBAZ.IR

In situations where there is a periodic renewal of susceptible people, such as on cruise ships and at camps, the facility may have to be closed until cleaning is complete. Although many state and local health departments require that food handlers with gastroenteritis not return to work until two to three days following recovery, this may not be an adequate length of time to prevent noroviral transmission.

The prevention of norovirus outbreaks include reducing contamination of water supplies with human waste and using high-level chlorination—at least 10 ppm for more than 30 minutes. Surveillance of shorelines for potential sources of fecal contamination and for boats that are dumping human waste may help prevent shellfish-associated norovirus outbreaks.

In 2004, researchers at Washington University (St. Louis, Missouri) became the first to grow a norovirus in a laboratory setting. They grew a mouse norovirus, with the goal of studying the virus and developing a vaccine against it. Research is ongoing in the early 2010s. New surveillance systems also are being developed to detect norovirus outbreaks at an early stage.

Nosebleed

Definition

A nosebleed is bleeding from the nose; the medical term for it is epistaxis.

Description

Unexpected bleeding from anywhere is cause for alarm. Persistent bleeding should always be investigated because it may be the earliest sign of cancer. Fortunately, nosebleeds are rarely a sign of cancer. A much more common cause of nosebleeds is injury from picking, blowing, or fisticuffs. People with hay **fever** have swollen membranes that are fragile and more likely to bleed.

Most nosebleeds (about 90%) come from the front of the septum, that plane of cartilage that separates the nostrils. These are called anterior nosebleeds. The lower front part of the septum has a mass of blood vessels on either side called Kiesselbach's plexus that is easy to injure. Nosebleeds from the more remote reaches of the nose are called posterior nosebleeds. They are less common, are less likely to have a benign cause, and are much harder to manage.

Nosebleeds are most likely to occur in children between the ages of two and 10 years, in part because younger children frequently insert small objects in the nose or pick at the tissues lining the nose. Nosebleeds in adolescents may indicate cocaine abuse. Nosebleeds in older adults may result from arteriosclerosis or high blood pressure.

KEY TERMS

Cautery—The use of heat, electricity, or chemicals to destroy tissue.

Embolization—A technique for stopping bleeding by introducing a substance into larger blood vessels that blocks or closes them.

Epistaxis—The medical term for nosebleed.

Kiesselbach's plexus—An area on the anterior part of the nasal septum that has a rich supply of blood vessels and is a common site of nosebleeds. It is named for Wilhelm Kiesselbach, a 19th-century German otolaryngologist.

Septum—The partition that separates the two nostrils. It consists of membranes, cartilage, and bone.

Styptic—Any remedy with an astringent and hemostatic (stopping bleeding) quality.

Causes and symptoms

Nosebleeds may result from a number of different causes:

- local infections (colds, sinus infections)
- systemic infections (scarlet fever, typhoid fever, malaria)
- drying of the membranes lining the nose, often during heating season in colder climates
- medications, most commonly, overuse of nasal decongestant sprays
- trauma (from foreign objects in the nose; scratching or picking with the fingers; or blunt trauma to the face)
- tumors in the nasopharynx or paranasal sinuses
- cocaine abuse
- bleeding disorders (leukemia, liver disease, hemophilia and other hereditary clotting disorders)

Treatment

The first treatment is to pinch the patient's nostrils together, have them sit forward, and ask them to stay that way for 5–10 minutes. This method usually stops nosebleeds originating in Kiesselbach's plexus. The patient should not tilt his or her head backward, as this position may cause blood to drip backward into the throat or windpipe. It is best to hold the head upright.

In the case of small children, the doctor may examine the inside of the nose to check for foreign bodies, evidence of scratching or picking, etc. Small foreign bodies (watch batteries, dried peas or beans, buttons, etc.) can be removed by suction if necessary. The doctor may also have to remove clotted blood by suction.

Bleeding that continues originates from the back of the nose in most cases and will flow down the throat. If that happens, emergency intervention is needed.

As an emergency procedure, the nose will be packed front and/or back with cotton gauze and a rubber balloon from a Foley catheter. This treatment is not comfortable. Having no place to flow, the blood should clot, giving the ear, nose and throat specialists (otorhinolaryngologists) a chance to find the source and permanently repair it. If the packing has to remain for any length of time, **antibiotics** and **pain** medication will be necessary—antibiotics because the sinuses will be plugged up and prone to infection. Nose packing may so interfere with breathing that the patient will need supplemental oxygen.

WWW.BOOKBAZ.IR

Newer options for controlling posterior nosebleeds include the use of Surgicel, Merocel, or other oxidized cellulose products that expand with moisture. These may control the bleeding without the need for bulky **nasal packing**.

Many bleeds are from small exposed blood vessels with no other disease. They can be destroyed by cautery, usually done by applying silver nitrate to the affected area. Larger vessels may not respond to cautery. The surgeon may have to tie them off, which is known as ligation. Another technique that is sometimes used with larger vessels is embolization, in which the doctor injects a chemical to block or close the blood vessel.

Alternatives

Estrogen cream, the same preparation used to revitalize vaginal tissue, can toughen fragile blood vessels in the anterior septum and forestall the need for cauterization. Botanical medicines known as styptics, which slow down and can stop bleeding, may be taken internally or applied topically. Some of the plants used are *Achillea* (yarrow), trillium, geranium, and shepherd's purse (*Capsella bursa-pastoris*). Homeopathic remedies can be one of the quickest and most effective treatments for epistaxis.

Prevention

Both before and after a nosebleed, the patient should blow the nose gently and avoid picking or scratching the tissues that line it. Children with recurrent nosebleeds during heating season may benefit from the use of a cool-mist vaporizer to humidify the bedroom at night, or from the application of a small quantity of petroleum jelly to the inside of each nostril. Treatment of hay fever helps reduce the fragility of the tissues.

Numbness and tingling

Definition

Numbness and tingling are decreased or abnormal sensations caused by altered sensory nerve function.

Demographics

People of all ages experience episodes of numbness and tingling; however, these generally become more common as people age. Episodes of numbness and tingling are more common among people with diabetes, **hypothyroidism**, **alcoholism**, **malnutrition**, or who experience mechanical **trauma**, especially to their limbs, neck, or spine.

Description

The feeling of having a foot "fall asleep" is a familiar one. This same combination of numbness and tingling can occur in any region of the body and may be caused by a wide variety of disorders. Sensations such as these, which occur without any associated stimulus, are called paresthesias. Other types of paresthesias include feelings of cold, warmth, burning, **itching**, and skin crawling.

Causes and symptoms

Causes

Sensation is carried to the brain by neurons (nerve cells) running from the outer parts of the body to the spinal cord in bundles called nerves. In the spinal cord, these neurons make connections with other neurons that run up to the brain. Paresthesias are caused by disturbances in the function of neurons in the sensory pathway. This disturbance can occur in the central nervous system (the brain and spinal cord), the nerve roots that are attached to the spinal cord, or the peripheral nervous system (nerves outside the brain and spinal cord).

Peripheral disturbances are the most common cause of paresthesias. "Falling asleep" occurs when the blood supply to a nerve is cut off—a condition called ischemia. Ischemia usually occurs when an artery is compressed as it passes through a tightly flexed joint. Sleeping with the arms above the head or sitting with the legs tightly crossed frequently cause numbness and tingling.

Direct compression of the nerve also causes paresthesias. Compression can be short-lived, as when a heavy backpack compresses the nerves passing across the shoulders. Compression may also be chronic. Chronic nerve compression occurs in entrapment syndromes. The most common example is **carpal tunnel syndrome**. Carpal tunnel syndrome occurs when the median nerve is compressed as it passes through a narrow channel in the wrist. Repetitive motion or prolonged vibration can cause the lining of the channel to swell and press on the nerve. Chronic nerve root compression, or radiculopathy, can occur in disk disease or spinal arthritis.

Other causes of paresthesias related to disorders of the peripheral nerves include:

- Metabolic or nutritional disturbances. These disturbances include diabetes, hypothyroidism (a condition caused by too little activity of the thyroid gland), alcoholism, malnutrition, and vitamin B_{12} deficiency.
- Trauma. Trauma includes injuries that crush, sever, or pull on nerves.
- Inflammation.
- Connective tissue disease. These diseases include arthritis, systemic lupus erythematosus (a chronic inflammatory disease that affects many systems of the body, including the nervous system), polyarteritis nodosa (a vascular disease that causes widespread inflammation and ischemia of small and medium-size arteries), and Sjögren's syndrome (a disorder marked by insufficient moisture in the tear ducts, salivary glands, and other glands).
- Toxins. Toxins include heavy metals (metallic elements such as arsenic, lead, and mercury which can, in large amounts, cause poisoning), certain antibiotics and chemotherapy agents, solvents, and overdose of pyridoxine (vitamin B_6).
- Malignancy.
- Infections. Infections include Lyme disease, human immunodeficiency virus (HIV), and leprosy.
- Hereditary disease. These diseases include Charcot-Marie-Tooth disease (a hereditary disorder that causes wasting of the leg muscles, resulting in malformation of the foot), porphyria (a group of inherited disorders in which there is abnormally increased production of substances called porphyrins), and Denny-Brown's syndrome (a hereditary disorder of the nerve root).

Paresthesias can also be caused by central nervous system disturbances, including **stroke**, TIA (**transient ischemic attack**), tumor, trauma, **multiple sclerosis**, or infection.

Symptoms

Sensory nerves supply or innervate particular regions of the body. Determining the distribution of symptoms is an important way to identify the nerves involved. For instance, the median nerve innervates the thumb, the first two fingers, half of the ring finger, and the part of the hand to which they connect. The ulnar nerve innervates the other half of the ring finger, the little finger, and the remainder of the hand. Distribution of symptoms may also aid diagnosis of the underlying disease. Diabetes usually causes a symmetrical "glove and stocking" distribution in the hands and feet. Multiple sclerosis may cause symptoms in several, widely separated areas.

Other symptoms may accompany paresthesias, depending on the type and severity of the nerve disturbance. For instance, weakness may accompany damage to nerves that carry both sensory and motor neurons. (Motor neurons are those that carry messages outward from the brain.)

Diagnosis

A careful history of the patient is needed for a diagnosis of paresthesias. The medical history should focus on the onset, duration, and location of symptoms. The history may also reveal current related medical problems and recent or past exposure to drugs, toxins, infection, or trauma. The family medical history may suggest a familial disorder. A work history may

WWW.BOOKBAZ.IR

KEY TERMS

Electromyography—A test that uses electrodes to record the electrical activity of muscle. The information gathered is used to diagnose neuromuscular disorders.

Motor nerve—Motor or efferent nerve cells carry impulses from the brain to muscle or organ tissue.

Nerve conduction velocity test—A test that measures the time it takes a nerve impulse to travel a specific distance over the nerve after electronic stimulation.

Nerve growth factor—A protein resembling insulin that affects growth and maintenance of nerve cells

Peripheral nervous system—The part of the nervous system that is outside the brain and spinal cord. Sensory, motor, and autonomic nerves are included.

Sensory nerves—Sensory or afferent nerves carry impulses of sensation from the periphery or outward parts of the body to the brain. Sensations include feelings, impressions, and awareness of the state of the body.

reveal repetitive motion, chronic vibration, or industrial chemical exposure.

The physical and neurological examination tests for distribution of symptoms and alterations in reflexes, sensation, or strength. The distribution of symptoms may be mapped by successive stimulation over the affected area of the body.

Lab tests for paresthesia may include blood tests and **urinalysis** to detect metabolic or nutritional abnormalities. Other tests are used to look for specific suspected causes. Nerve conduction velocity tests, **electromyography**, and imaging studies of the affected area may be employed. Nerve biopsy may be indicated in selected cases.

Treatment

Treatment of paresthesias depends on the underlying cause. For limbs that have "fallen asleep," restoring circulation by stretching, exercising, or massaging the affected limb can quickly dissipate the numbness and tingling. If the paresthesia is caused by a chronic disease such as diabetes or occurs as a complication of treatments such as **chemotherapy**, most treatments are aimed at relieving symptoms. Anti-inflammatory drugs such as **aspirin** or ibuprofen are recommended if symptoms are mild. In more difficult cases, **antidepressant drugs** such as amitriptyline (Elavil) are sometimes prescribed. These drugs are given at a much lower dosage for this purpose than for relief of depression. They are thought to help because they alter the body's perception of **pain**. In severe cases, opium derivatives such as codeine can be prescribed. Currently trials are being done to determine whether treatment with human nerve growth factor will be effective in regenerating the damaged nerves.

Alternatives

Several alternative treatments are available to help relieve symptoms of paresthesia. Nutritional therapy includes supplementation with B complex **vitamins**, especially vitamin B_{12} (intramuscular injection of vitamin B_{12} is most effective). Vitamin supplements should be used cautiously however. Overdose of vitamin B_6 is one of the causes of paresthesias. People experiencing paresthesia should also avoid alcohol. **Acupuncture** and massage are said to relieve symptoms. Self-massage with aromatic oils is sometimes helpful. The application of topical ointments containing capsaicin, the substance that makes hot peppers hot, provides relief for some. It may also be helpful to wear loosely fitting shoes and clothing. None of these alternatives should be used in place of traditional therapy for the underlying condition.

Prognosis

Treating the underlying disorder may reduce the occurrence of paresthesias. Paresthesias resulting from damaged nerves may persist throughout or even beyond the recovery period. The overall prognosis depends on the cause.

Prevention

Preventing the underlying disorder may reduce the incidence of paresthesias. For those with frequent paresthesias caused by ischemia, changes in posture may help.

Nutrition

Definition

Nutrition is the sum of all the processes by which food enters and is utilized by the body. Nutrients include protein, carbohydrates, fats, **vitamins**, **minerals**, and water. Fiber in foods helps prevent disease and control weight.

Purpose

Nutrition is essential to life. It is required for growth and development from infancy through young adulthood and throughout life to provide energy and maintain bodily tissues and functions. Good nutrition promotes health and helps prevent **obesity** and disease. Nutrition is especially important during **pregnancy** and childhood to prevent growth retardation. Childhood and **adolescent nutrition** can have major ramifications on health in later life.

Demographics

Throughout much of the world families struggle to obtain adequate nutrition. In the United States and other developed countries nutrition is more often a matter of choice. According to the Centers for Disease Control (CDC), American society has become "obesogenic," with increased consumption of non-nutritional foods. Only 25% of Americans consume at least five daily servings of fruits and vegetables—the cornerstones of good nutrition. Americans are also eating more restaurant and fast food than in the past, along with larger portions and other changes in meal patterns and frequency.

Pediatric

The nutritional status and health of American children and adolescents has declined in recent years:

- The Healthy Eating Index from the U.S. Department of Agriculture (USDA) has found that among children aged two through nine, 60–80% have diets in need of improvement and 4–8% have poor diets, with 63% eating too little fruit and 78% eating too few vegetables.
- Only 21% of high school students report eating five or more daily servings of fruits and vegetables (other than fried potatoes and chips).
- Whole grains account for only 14% of the total daily grain consumption of children and adolescents.
- Only 39% of children aged two through 17 meet dietary recommendations for fiber (fruits, vegetables, dried beans and peas, and whole grains).
- More than 60% of children and teens eat too much saturated fat.
- Almost two-thirds of teens eat more than the recommended amount of total fat.
- Most teens eat too much processed, prepared, and junk foods.
- Among adolescent girls, 85% do not consume adequate calcium. Milk consumption by teenage girls has decreased 36% in recent decades, while soft-drink consumption has almost doubled among girls and almost tripled among adolescent boys.
- Eating disorders are the third most common chronic illness in adolescent girls, affecting as many as 5%.

Geriatric

According to a report by the Merck Institute of Aging and Health and the CDC, two-thirds of older Americans fail to practice good nutrition. Almost 90% of Americans over the age of 65 have one or more degenerative disorders that may have been prevented by better nutrition.

Pregnant or breastfeeding

Breast milk is ideal nutrition for most infants. **Breastfeeding** has increased significantly in the United States in recent decades, from 60% in 1993–1994 to 77% presently. Breastfeeding rates by black Americans increased from 36% in 1993–1994 to 59% in 2008. Breastfeeding rates are significantly higher among mothers with higher incomes and those aged 30 and over.

WWW.BOOKBAZ.IR

Description

The human body absorbs many different nutrients from food. A good nutrition plan includes a variety of foods from the different food groups, with adequate amounts of the nutrients in each group. Keys to good nutrition include:

- fruits, vegetables, and whole grains
- protein, fiber, calcium, iron, magnesium, potassium, and vitamins A, C, and E
- low-fat dairy products, lean meats, poultry, fish, and beans
- no more than 20–35% of total calories from fat, mostly from polyunsaturated and monounsaturated fats
- plenty of water
- more fluids and carbohydrates from fruits and whole grains for athletes and other physically active individuals
- additional vitamin D from fortified foods and/or supplements for older adults, those with darker skin, and people with insufficient exposure to sunlight
- limited salt (less than about one teaspoon daily for most people), added sugar, saturated fat, trans fat, cholesterol, and alcohol (no more than one drink per day for women and two for men)

Vitamins are required for regulating metabolism and maintaining normal growth and functioning. Minerals are vital for building tissue, muscles, and bones, and for many life-supporting systems, including hormones, oxygen transport, and enzyme function. Although foods are the preferred source of these nutrients, they can also be obtained from **nutritional supplements**.

In 2005 the USDA and the U.S. Department of Health and Human Services revised their *Dietary Guidelines for Americans*, with caloric requirements and servings adjusted for gender, age, and physical activity. The guidelines also make recommendations for special populations and incorporate the 2006 DASH (Dietary Approaches to Stop **Hypertension**) Eating Plan developed by the U.S. National Heart, Lung and Blood Institute. The USDA revised the traditional food pyramid to be customizable for individuals. The new guidelines and pyramid focus on balancing calories consumed and utilized by the body, with managed portions from the different food groups and the avoidance of high-sugar and high-fat foods.

USDA/DASH recommendations for a 2,000-calorie daily diet include:

- fruit group: 2–2.5 cups (4–5 servings) of fresh, frozen, canned, or dried fruit, with only limited juice
- vegetable group: 2–2.5 cups (4–5 servings)
- grain group: 6–8 ounce-equivalents of cereal, bread, crackers, rice, or pasta; with at least 50% whole grain
- meat and beans group: 5.5–6 ounce-equivalents of baked, broiled, or grilled lean meat, poultry, or fish, eggs, nuts, seeds, beans, peas, or tofu
- milk group: 2–3 cups low-fat/fat-free milk, yogurt, or cheese, or lactose-free, calcium-fortified products
- oils: 2–6 teaspoons
- discretionary: 267 calories; for example, solid fats (saturated fat such as butter, margarine, shortening, or lard) or added sugar

The vegetable group includes:

- dark greens, such as broccoli and leafy greens: three cups per week
- orange vegetables, such as carrots and sweet potatoes: two cups per week
- legumes, such as pinto or kidney beans, split peas, or lentils: three cups per week
- starchy vegetables: three cups per week
- other vegetables: 6.5 cups per week

Results

In addition to its essential role in growth and development, maintenance of bodily functions, and energy supply, good nutrition helps prevent weight gain with calories that are high in nutrients other than sugars and fats. Good nutrition also helps prevent various disorders including:

- dental caries
- iron-deficiency anemia
- osteoporosis
- hypertension
- heart disease
- type 2 diabetes
- some types of cancer

Precautions

In general:

- Fresh foods are usually more nutritious than packaged and processed foods.
- Fast and processed foods contain excess fat and sodium and high amounts of sugar, as well as artificial preservatives, and other additives.
- Fast and processed foods are deficient in fiber and essential vitamins and minerals, such as vitamin A,

riboflavin, folic acid, vitamin E, calcium, magnesium, and potassium.

- It is difficult to gauge nutrition and calories when eating out and buying packaged foods.
- Vegetarians need to choose carefully from the basic foods groups to achieve recommended nutrient intakes, especially of protein, vitamins, and iron.
- Iron-deficiency anemia is very common in women. The recommended iron intake is 15–18 mg daily for females. Good sources of iron include dark-green leafy vegetables, legumes, iron-fortified breads and cereals, and red meat.
- Many adults do not obtain enough calcium from their diets, which can lead to osteoporosis in later life. Women aged 19–50 should consume 1,000 mg of calcium daily. Women over 50 require 1,200 mg. Good sources of calcium include dark-green leafy vegetables, calcium-fortified orange juice, bread, cereal, fish, and low-fat dairy products.
- Although nutritional supplementation is sometimes necessary, if possible, nutrients should come from food. Excessive use of vitamin and mineral supplements can lead to serious health problems.
- Diets should not be radically altered except under medical supervision.

Pediatric

Childhood nutrition requires adequate essential nutrients, fiber, and calories to maintain proper growth, maximize cognitive development, and promote health, while preventing excess weight gain. Poor nutrition in adolescence can cause growth and developmental problems and long-term complications including obesity, **heart disease**, and **osteoporosis**. Children's **diets** should include a variety of foods with high nutrient-to-calorie ratios. In addition:

- At age two, 25–33% of grains should be whole-grain, gradually increasing to 50% by age five.
- The average adolescent protein requirement is about 300 mg per 0.4 in (1 cm) of height.
- Physically active adolescents require more fluids and more carbohydrates from fruit and whole grains.
- Requirements for vitamins and minerals increase during adolescence. Teenagers require 1,300 mg of calcium daily. Boys require 10-12 mg of iron and 15 mg of zinc daily. Girls require 15 mg of iron and 12 mg of zinc.
- Vegan and macrobiotic diets for adolescents may require nutritional supplements.

Geriatric

Various factors can interfere with nutrition in the elderly:

- medical conditions and/or medications
- reduced capacity to absorb and utilize nutrients
- oral/dental problems or difficulty chewing or swallowing
- gastrointestinal disturbances
- loss of appetite
- diminishing taste and smell
- changes in taste preferences
- loss of dexterity
- social isolation, loneliness, or depression
- economic limitations
- lack of cooking skills or desire to cook
- inadequate knowledge of nutrition
- dementia

The rate of metabolism can decline by as much as 30% over a lifetime and lean muscle mass can decrease by as much as 25% in the elderly, accompanied by an increase in body fat. Therefore, seniors need foods with high nutrient-to-calorie ratios. Although caloric requirements vary greatly, it has been recommended that, after age 50, men reduce their daily intake by 600 calories and women by 300 calories. Because seniors eat less and take in fewer calories, they also consume fewer vitamins and minerals, even though the body's need for some micronutrients may actually increase with age. This is especially true for **vitamin D** and **calcium**. A single daily multivitamin/mineral supplement can address nutritional gaps.

Other nutritional recommendations for seniors include:

- adequate protein for immune system health and maintenance and repair of body tissues
- dietary fiber from fruits, vegetables, beans, nuts, seeds, brown rice, and whole grains
- only small amounts of fats, oils, and sweets
- no more than 1,500 mg of sodium daily from all food sources (two-thirds of a teaspoon of table salt)
- adequate fluids—the elderly can easily become dehydrated
- vitamin B_{12} from fortified foods or supplements
- potassium from leafy green vegetables, tomatoes, bananas, and root vegetables such as potatoes to counter the effects of salt on blood pressure

WWW.BOOKBAZ.IR

KEY TERMS

Calorie—A unit of food energy.

Carbohydrate—Sugars, starches, celluloses, and gums that are a major source of calories from foods.

Cholesterol—A fat-soluble steroid alcohol (sterol) found in animal fats and oils, and produced in the body from saturated fats. Cholesterol is required to produce vitamin D and various hormones and for the formation of cell membranes. High cholesterol levels contribute to the development of atherosclerosis.

Fat—Molecules composed of fatty acids and glycerol; the slowest utilized source of energy, but the most energy-efficient form of food. Each gram of fat supplies about nine calories, more than twice that supplied by the same amount of protein or carbohydrate.

Monounsaturated fat—Fats that contain one double or triple bond per molecule; examples include canola oil and olive oil.

Polyunsaturated fat—Fats that contain two or more double or triple bonds per molecule; examples include fish, safflower, sunflower, corn, and soybean oils.

Protein—Chains of amino acids that are essential constituents of all living cells and include structural components, enzymes, hormones, and antibodies.

Saturated fat—Fat molecules that contain only single bonds; examples include whole milk, cream, palm and coconut oils, and solid fats such as cheese, butter, and meat.

Trans fat—Fat that is produced by hydrogenation during food processing; trans fats increase bad cholesterol and decrease good cholesterol.

Pregnant or breastfeeding

Women have special nutritional needs during menstruation, pregnancy, **lactation**, and **menopause**. Pregnant and breastfeeding women have increased requirements for calories and for most nutrients. Pregnant and breastfeeding teenagers have even higher nutritional requirements than other pregnant women. Pregnant women should consume iron-rich plant foods and vitamin-C-rich foods that aid in the absorption of iron. **Folic acid**, a B vitamin, is particularly important during pregnancy, since it helps protect against brain and spinal cord **birth defects**. All women of childbearing age should consume 400 micrograms (µg) of folic acid daily and 600 µg during pregnancy. Pregnancy and breastfeeding deplete maternal calcium. Pregnant and lactating adult women should consume 1,000 mg of calcium daily. Pregnant and lactating teenagers require 1,300 mg.

Hormonal changes during pregnancy can trigger **gestational diabetes**, characterized by high levels of sugar in the blood. Changes in diet and **exercise** are often sufficient to keep blood sugar levels within the normal range. Women who experience gestational diabetes are more likely to develop type 2 diabetes later in life.

Other conditions and allergies

Many people with **allergies** or medical conditions require special diets, such as a low-fat, low-cholesterol diet for heart disease, a low-sodium diet for high blood pressure, or a low-calorie diet for weight reduction. Chronic illnesses, such as diabetes, as well as substance abuse, also create special nutritional requirements.

Margaret Alic, PhD

Nutrition and mental health

Definition

Mental health problems are believed to result from a combination of factors, including genetics, age, and environmental influences, but there is also increasing evidence that food and **nutrition** may play a role. Evidence suggests that food may contribute to the prevention, progression, and management of several mental health disorders, including depression, **anxiety**, **schizophrenia**, **attention deficit hyperactivity disorder (ADHD)**, and Alzheimer's disease. Many people diagnosed with mental health conditions have been found to have low intakes of specific nutrients, but it is difficult to know whether these are causes or effects of the diagnoses. Research is ongoing, but while the role of nutrition in mental health has yet to be fully understood, it is generally accepted that diet has some influence on overall mood, brain function, and behavior.

Purpose

Food plays an important role in physical and emotional well-being at every stage of life, and a number of anecdotal, clinical, and controlled studies highlight the importance of nutrition in maintaining positive mental health. Mental health may be influenced by several dietary factors, including overall intake of calories, macronutrients (proteins, carbohydrates, and fats), alcohol, and **vitamins** and **minerals**. Often deficiencies of multiple nutrients—rather than a single nutrient—are responsible for changes in brain functioning. In the United States and other developed countries, **alcoholism** is often the cause of nutritional deficiencies that affect mental functioning. Certain diseases can also result in nutritional deficiencies by affecting the absorption of nutrients into the body or by increasing nutritional requirements.

In addition to good nutrition, a well-balanced **exercise** program can improve general health, build endurance, and enhance emotional well-being.

Description

The World Health Organization (WHO) estimates that approximately 450 million people have a diagnosable mental disorder, with many more experiencing mental problems. The number and type of mental illnesses reported vary from country to country depending on cultural, reporting, and intrinsic differences. Some statistics suggest that one in four people in the United States is likely to experience a mental health disorder at some point, with rates potentially higher in other countries.

Diagnosis of a mental health disorder is usually made by a trained clinician, such as a psychiatrist, psychologist, or family physician. Confirmation of a diagnosis usually is made following completion of standardized assessment tools and a full psychiatric assessment.

Nutrition and the brain

In order to understand the role individual nutrients play in the body, it is important to briefly look at the structure of the brain and how it functions. The brain

WWW.BOOKBAZ.IR

contains billions of nerve cells that allow it to communicate with itself and other parts of the body. In order to properly transmit nerve impulses, nerve cells must be coated with a material called myelin, which contains a high level of fat derived from diet. Chemicals called neurotransmitters help the nerve cells communicate with each other. These neurotransmitters are composed of amino acids (proteins), which are also often derived from the diet. Serotonin is one important neurotransmitter derived from an amino acid called tryptophan. Other transmitters include acetylcholine, dopamine, epinephrine (adrenaline), norepinephrine, and 4-aminobutyrate (GABA). These neurotransmitters impact anxiety, depression, memory, and overall cognitive function. It is suggested that the excessive consumption of certain foods can decrease the effectiveness of these neurotransmitters in the brain, while conversely, other foods can help maintain an efficient balance of neurotransmitters. Some scientists also believe that foods high in **antioxidants** may help protect the cells in the brain from damage.

Energy (calorie) intake

Energy, often referred to as the calorie content of a food, is derived from the carbohydrate, protein, and fat found in foods and beverages. Although vitamins and minerals are essential to the body, they provide no energy. The human brain is metabolically very active and uses about 20–30% of a person's energy intake at rest. Individuals who do not eat adequate amounts of calories from food to meet their energy requirements will experience changes in mental functioning. Skipping breakfast is associated with lower fluency and problem-solving ability, especially in individuals who are already slightly malnourished. A hungry person may also experience lack of energy or motivation.

Chronic hunger and energy deprivation profoundly affect mood and responsiveness. The body responds to energy deprivation by shutting or slowing down nonessential functions and altering activity levels, hormonal levels, oxygen and nutrient transport, the body's ability to fight infection, and many other functions that directly or indirectly affect brain function. People with a consistently low energy intake often feel apathetic, sad, or hopeless.

Developing fetuses and young infants are particularly susceptible to brain damage from **malnutrition**. The extent of the damage depends on the timing of the energy deprivation in relation to stage of development. Malnutrition early in life has been associated with below-normal intelligence and functional and cognitive defects. Similarly, studies have shown that people suffering **traumatic brain injury** face the best chance of **rehabilitation** when placed on a high-calorie, high-protein diet.

Proteins and amino acids

Amino acids are the building blocks of protein. The human body can manufacture some of the amino acids, but there are eight essential amino acids that must be supplied in the diet. A complete or high-quality protein contains all eight of the essential amino acids in the amounts needed by the body. Foods rich in high-quality protein include meats, milk and other dairy products, and eggs. Dried beans, peas, grains, and nuts and seeds also contain protein, although the protein in these plant foods may be low in one or more essential amino acid. Generally, combining any two types of plant protein foods together will yield a complete, high-quality protein. For example, a peanut butter and jelly sandwich combines grain protein from the bread with nut protein from the peanut butter to yield a complete protein. A bean and corn dish, such as refried beans in a corn tortilla, combines bean and grain protein for another complete protein combination.

The most widely researched amino acid is tryptophan, which is used by the body to produce the neurotransmitter serotonin. Serotonin plays a role in mood, eating patterns, and sleep patterns. One of the features of depression is a reduction in the amount of serotonin in the brain, though it is not known whether this decrease is a cause or effect of the condition. Tryptophan is found in many foods, including eggs, turkey, and beans. However, to convert tryptophan to serotonin, the body requires certain other enzymes, vitamins, and minerals. Absence of any of these essential components may affect the body's ability to manufacture serotonin.

Some diseases can cause a buildup of certain amino acids in the blood, leading to brain damage and mental defects. A buildup of the amino acid phenylalanine in individuals with a disease called **phenylketonuria** (PKU) can cause brain damage and **intellectual disability**.

Carbohydrates

Carbohydrates include starches, naturally occurring and refined sugars, and dietary fiber. Foods rich in starches and dietary fiber include grain products like breads, rice, pasta, and cereals, especially whole-grain products; fruits; and vegetables, especially starchy vegetables like potatoes. Carbohydrates significantly affect mood and behavior. Eating a meal high in carbohydrates triggers the release of a hormone called insulin in

the body. Insulin helps let blood sugar (glucose) into cells, where it can be used for energy, but it also has other effects in the body. As insulin levels rise, more tryptophan enters the brain, resulting in higher levels of serotonin. The increase in serotonin in the brain enhances mood and produces a sedating effect, including feelings of relaxation and sleepiness. This effect is partly responsible for the drowsiness some people experience after a large meal.

Fats

ESSENTIAL FATTY ACIDS. Fat is essential for life. The brain is composed of a high percentage of fat, much of which comes from the essential fatty acids (EFAs) omega-3 and omega-6. These are called essential because they cannot be made in the body and must be obtained from the diet. These EFAs are a vital part of the structure of the brain cells and are important for promoting communication between the cells in the brain.

Studies suggest that **omega-3 fatty acids** may have positive protective benefits for the heart, and more recently researchers have become interested in the potential benefits of omega-3 in behavior and positive mental health. However, there has been wide variation in the outcomes of studies—some researchers who have reviewed the evidence suggest positive effects on mood, while others discount it. One study suggested that the levels of depression among people living in the Arctic and Subarctic regions rose at the same time that traditional **diets**, which were high in EFAs, were being replaced by more processed foods. However, many other factors, including cultural changes, could have played a role in this finding.

Other researchers have investigated a possible relationship between diet and Alzheimer's disease, schizophrenia, and other cognitive disorders. Research in this area is still new, and no definitive conclusions can be drawn. In one study, 53% of bipolar patients on placebo (olive oil) became ill again within four months, while none of the patients who were given 9.6 g daily of omega-3 fatty acids (as fish oil) did. A 25% decrease in schizophrenic symptoms was observed in patients receiving eicosapentaenoic acid (EPA), one of the omega-3 fatty acids contained in fish oil. However, some studies have indicated a relationship between higher intakes of fat and increased incidence of Alzheimer's disease. Other research suggests a possible link between lower levels of polyunsaturated fatty acids (PUFAs) and schizophrenia.

Sources of omega-3 include oily fish, such as mackerel, pilchards, sardines, fresh tuna, salmon, herring, anchovies, kippers, whitebait, and trout. Vegetable oils, including linseed, flaxseed, canola (rapeseed), and walnut oil, also contain omega-3, but it is not yet clear whether this form is as effective.

SATURATED FATS. Saturated fat and *trans* fatty acids (also called partially hydrogenated; fats or oils) have achieved notoriety for their apparent role in reducing levels of HDL **cholesterol** (the "good" cholesterol). These fats are considered to increase a person's risk of **heart disease**, atherosclerosis (clogged arteries), and other diseases. Atherosclerosis can decrease blood flow to the brain, impairing brain functioning. If blood flow to the brain is blocked, a **stroke** occurs.

Although numerous studies clearly document the benefits of a cholesterol-lowering diet for the reduction of heart disease risk, some studies suggest that reducing fat and cholesterol in the diet may deplete brain serotonin levels, causing mood changes, anger, and aggressive behavior. Some **low-carbohydrate diets**, such as the "South Beach Diet," have achieved popularity in part because of their link with beneficial changes in cholesterol levels.

Vitamins

VITAMIN A. **Vitamin A** is a fat-soluble vitamin found in meats, fish, and eggs. A form of vitamin A, beta-carotene, is found in orange and green leafy vegetables, such as carrots, yellow squash, and spinach. **Headache** and increased pressure in the head are associated with both deficient and excess vitamin A intake. Among other effects, excess vitamin A intake can cause **fatigue**, irritability, and loss of appetite. Generally, doses must exceed 25,000 international units (IU) of vitamin A over several months to develop such symptoms.

VITAMIN E. **Vitamin E** is another fat-soluble vitamin found in plant oils, green leafy vegetables, and fortified breakfast cereals. Vitamin E deficiency is very rare, except in disorders that impair absorption of fat-soluble vitamins in the body, such as **cystic fibrosis** and liver diseases.

Vitamin E deficiency causes changes in red blood cells and nerve tissues, resulting in **dizziness**, vision and sensory changes, and muscle weakness. If left untreated, the nerve damage from vitamin E deficiency can be irreversible. Because it is an antioxidant, vitamin E has also been studied for treatment of neurological conditions, such as Parkinson's and Alzheimer's disease. Vitamin E and other antioxidants, such as vitamin C, had shown some promise in treating Alzheimer's, but larger analyses found no beneficial effect of vitamin E supplements. Research on vitamin E and other antioxidants is ongoing.

WWW.BOOKBAZ.IR

VITAMIN B_6. Vitamin B_6, also known as pyridoxine, is found in many plant and animal foods, including chicken, fish, pork, whole-wheat products, brown rice, and some fruits and vegetables. It is needed by the body to produce most of the brain's neurotransmitters and is also involved in hormone production. In healthy individuals, deficiency of vitamin B_6 is rare, but certain drugs, including some **antidepressant drugs**, can induce vitamin B_6 deficiency. Symptoms of vitamin B_6 deficiency include mental changes, such as fatigue, nervousness, irritability, depression, **insomnia**, dizziness, and nerve changes.

Excess of vitamin B_6 also causes mental changes. Vitamin B_6 supplements are used by many individuals for a variety of conditions, including **carpal tunnel syndrome**, **premenstrual syndrome**, and fibrocystic breast disease. It is also included in excessive amounts in **energy drinks** and tablets. Doses of 500 mg per day or more can cause nerve damage, dizziness, sensory loss, and numbness.

VITAMIN B_{12}. Vitamin B_{12} is found only in foods of animal origin, such as milk, meat, or eggs. Strict vegans who consume no animal-based foods need to supplement their diet with vitamin B_{12} to meet the body's need for this nutrient. Vitamin B_{12} is needed to maintain the outer coating of nerve cells, called the myelin sheath. Inadequate myelin results in nerve damage and impaired brain function. Vitamin B_{12} deficiency can go undetected in individuals for years, but it eventually causes low blood iron, irreversible nerve damage, **dementia**, and brain atrophy.

FOLIC ACID. **Folic acid** is another B vitamin, found in liver, yeast, asparagus, dried beans and peas, wheat, broccoli, and some nuts. Many grain products are also fortified with folic acid. In the United States, alcoholism is a common cause of folic acid deficiency.

Folic acid is involved in protein metabolism in the body and in the metabolism of some amino acids, particularly the amino acid methionine. When folic acid levels in the body are low, methionine cannot be metabolized properly, and levels of another chemical, **homocysteine**, build up in the blood. High blood homocysteine levels increase the risk of heart disease and stroke.

Even modest folic acid deficiency in pregnant women causes an increased risk of neural tube defects, such as **spina bifida**, in developing fetuses. Folic acid deficiency also increases the risk of stroke. Some studies suggest that folic acid deficiency leads to a range of mental disorders, including depression, but this concept remains controversial. Folic acid deficiency can, however, lower levels of serotonin in the brain.

THIAMIN. Thiamin is a B vitamin found in enriched grain products, pork, legumes, nuts, seeds, and organ meats. It is intricately involved with metabolizing glucose. Glucose is the brain's primary energy source. Thiamin is also needed to make several neurotransmitters.

Alcoholism is often associated with thiamin deficiency. Alcohol interferes with thiamin metabolism in the body, and diets high in alcohol are often deficient in vitamins and minerals. Individuals with a thiamin deficiency can develop Wernicke-Korsakoff syndrome, which is characterized by confusion, mental changes, abnormal eye movements, and unsteadiness that can progress to severe **memory loss**.

NIACIN. The B-vitamin niacin is found in enriched grains, meat, fish, wheat bran, asparagus, and peanuts. The body can also make niacin from tryptophan. Niacin helps with the release of energy in the body from carbohydrates, proteins, and fats. Niacin deficiency is linked to many mental symptoms including irritability, headaches, loss of memory, inability to sleep, and emotional instability. Severe niacin deficiency progresses to a condition called **pellagra**, which is characterized by the "four D's": **dermatitis** (a rash resembling a **sunburn**), **diarrhea**, dementia, and, ultimately, death. The mental symptoms in pellagra can progress to **psychosis**, **delirium**, and **coma**.

Minerals

IRON. Iron is a trace mineral that is essential for formation of hemoglobin, the substance that carries oxygen to cells throughout the body. Iron is found in meat, poultry, and fish. Another form of iron that is not as well absorbed as the form in animal foods is found in whole or enriched grains, green leafy vegetables, dried beans and peas, and dried fruits. Consuming a food rich in vitamin C, such as orange juice, at the same time as an iron-containing plant food will enhance iron absorption from the food.

Iron deficiency can lead to anemia, which means that the ability of the body to transport oxygen around the body is compromised. This can result in fatigue, lethargy, and poor mood. Iron deficiency during the first two years of life can lead to permanent brain damage.

SELENIUM. Selenium plays a role in immune system functioning, reproduction, and thyroid hormone metabolism. Some research studies suggest that selenium may have a role in mood and energy levels, and that people with a low selenium intake are more likely to be anxious, depressed, and tired; however, it is not clear whether low selenium levels contribute to or are

caused by these symptoms. Sources of selenium include walnuts and brazil nuts, seafood, chicken, beef, bran, broccoli, mushrooms, onions, wheat germ, and whole-grain products.

Although selenium deficiency is very rare, selenium toxicity has occurred in regions of the world with high selenium soil content. Selenium toxicity causes nervous system changes, fatigue, and irritability.

MAGNESIUM. Magnesium is found in green leafy vegetables, whole grains, nuts, seeds, and bananas. In addition to its involvement in bone structure, magnesium aids in the transmission of nerve impulses. Magnesium deficiency can cause restlessness, nervousness, muscular twitching, and unsteadiness. Acute magnesium deficiency can progress to apathy, delirium, convulsions, coma, and death.

MANGANESE. Manganese is a trace mineral found in whole grains, nuts, and (to a lesser extent) fruits and vegetables. It is involved in carbohydrate metabolism and brain functioning. Although very rare, manganese deficiency can cause abnormalities in brain function. Groups of miners of manganese in South America have developed manganese toxicity, with neurological symptoms similar to Parkinson's disease.

COPPER. The richest sources of the trace mineral copper in the diet are organ meats, seafood, nuts, seeds, whole-grain breads and cereals, and chocolate. In addition to other functions, copper is involved in iron metabolism in the body and in brain functioning. Deficiency of copper causes anemia, with inadequate oxygen delivery to the brain and other organs. Copper deficiency also impairs brain functioning and immune system response, including changes in certain chemical receptors in the brain and lowered levels of neurotransmitters.

ZINC. Zinc is found in red meats, liver, eggs, dairy products, vegetables, and some seafood. Among other functions, zinc is involved in maintaining cell membranes and protecting cells from damage. Zinc deficiency can cause neurological impairment, influencing appetite, taste, smell, and vision. It has also been associated with apathy, irritability, jitteriness, and fatigue.

Antioxidants

Studies of schizophrenia suggest that people with schizophrenia many have lower than normal levels of antioxidants in the brain, indicating that their brain cells may be more vulnerable to oxidation and damage. However, further research is required before any correlations can be made. Similar research into the role of antioxidants in the prevention of Alzheimer's disease is also ongoing.

Water

Water makes up more than three-quarters of the brain and is an essential element in ensuring the chemical processes in the body work efficiently. Water is lost daily through waste, sweat, and urine. Replacement of these fluids is essential. Average fluid requirements for adults are approximately 35 mL per kg (1.18 oz per 2.2 lb) per day. Signs of **dehydration** include tiredness, restlessness, irritable behavior, weakness, **constipation**, loss of concentration and headaches. More severe symptoms can include low blood pressure, **fainting**, and, on rare occasions, **heart failure**.

Water is one of the best sources of fluid for the body. Other fluids include fruit juice, milk, and sports drinks. Tea and coffee can also contribute to daily fluid intake, but excess **caffeine** and alcohol can have a diuretic effect and exacerbate dehydration.

Alcohol and caffeine

High alcohol or caffeine intake can interfere with normal sleep patterns and affect mood. Alcoholism is one of the most common causes of nutritional deficiencies in developed countries. Alcoholic beverages provide energy but virtually no vitamins or minerals. A person who consumes large amounts of alcohol will meet their calorie needs but not their vitamin and mineral needs. In addition, extra amounts of certain vitamins are needed to break down alcohol in the body, further contributing to nutrient deficiencies.

A small number of mental health disorders are seen as relating directly to food and nutrition. The American Psychiatric Association recognizes seven disorders related to alcohol and caffeine intake: alcohol use disorder, alcohol intoxication, alcohol withdrawal, alcohol-induced disorder not elsewhere classified, caffeine intoxication, caffeine withdrawal, and caffeine-induced disorder not elsewhere classified.

Exercise

Lifestyle factors, including exercise, are increasingly seen as first-line treatments for people with symptoms of depression, anxiety, and many other common mental health conditions. Interventions that include nutritional therapies often are undertaken in conjunction with more traditional treatments, such as cognitive behavior therapy (CBT).

Precautions

While there is some evidence that good nutrition can help prevent some mental health problems, good nutrition is not in itself a treatment. Mental health

WWW.BOOKBAZ.IR

KEY TERMS

Antioxidant—A molecule that prevents oxidation. In the body, antioxidants attach to other molecules called free radicals and prevent the free radicals from causing damage to cell walls, DNA, and other parts of the cell. Vitamin E, vitamin C, and beta carotene are common antioxidants.

Depression—A mental state characterized by feelings of sadness, despair, and discouragement.

Dopamine—A chemical in brain tissue that serves to transmit nerve impulses (a neurotransmitter) and helps to regulate movement and emotions.

Fat-soluble vitamin—A vitamin that dissolves in, and can be stored in, body fat or the liver.

Fatty acids—Complex molecules found in fats and oils. Essential fatty acids are fatty acids that the body needs but cannot synthesize. Essential fatty acids are made by plants and must be present in the diet to maintain health.

Hormone—A chemical messenger that is produced by one type of cell and travels through the bloodstream to change the metabolism of a different type of cell.

Mineral—An inorganic substance found in the earth that is necessary in small quantities for the body to maintain health. Examples include zinc, copper, iron.

Neurotransmitter—One of a group of chemicals secreted by a nerve cell (neuron) to carry a chemical message to another nerve cell, often as a way of transmitting a nerve impulse. Examples of neurotransmitters include acetylcholine, dopamine, serotonin, and norepinephrine.

Norepinephrine—A hormone released by nerve cells and the adrenal medulla that causes constriction of blood vessels. Norepinephrine also functions as a neurotransmitter.

Schizophrenia—A severe mental disorder in which a person loses touch with reality and may have illogical thoughts, delusions, hallucinations, behavioral problems and other disturbances.

Serotonin—A widely distributed neurotransmitter that is found in blood platelets, the lining of the digestive tract, and the brain, and that works in combination with norepinephrine. It causes very powerful contractions of smooth muscle and is associated with mood, attention, emotions, and sleep. Low levels of serotonin are associated with depression.

disorders are caused by a complex interaction of factors, in which there is increasing evidence that nutrition is likely to play a role. Good nutrition can promote good physical health, which has also been linked to improved mental health outcomes.

Complications

Some changes in mental health may be caused by an underlying medical condition. People experiencing mental health–related symptoms should discuss all concerns with a doctor or psychiatrist.

Parental concerns

Some researchers and many parents claim that a high sugar intake causes hyperactivity in children. Carefully controlled studies do not support this conclusion. High sugar intake is associated with dental problems. Further, foods high in refined sugars are often low in other nutrients, making it prudent to limit their consumption.

Good nutrition is extremely important in helping school-aged children reach their academic potential; research studies suggest that when children are hungry, behavior problems increase. It has been suggested that ensuring good **childhood nutrition** can help reduce problem behaviors, such as fighting and class absences, while simultaneously increasing attention and focus in the classroom. One study has suggested that taking vitamin and omega-3 fatty acid dietary supplements can positively affect the behavior of adult offenders and reduce antisocial behavior; however, further studies are necessary to replicate these findings among the general population.

Nutritional supplements

Definition

Nutritional supplements include **vitamins**, **minerals**, herbs, meal supplements, sports **nutrition** products, natural food supplements, and other related products used to boost the nutritional content of the diet.

Purpose

Nutritional supplements are used for many purposes. They can be added to the diet to boost overall health and energy, to provide immune system support and reduce the risks of illness and age-related conditions, to improve performance in athletic and mental activities, and to support the healing process during illness and disease. Although some supplements may be prescribed by a doctor or used for medical purposes, most of these products are regulated by the U.S. Food and Drug Administration (FDA) as food products, not as drugs. This means that they do not have to meet the strict standards that drugs do.

WWW.BOOKBAZ.IR

Description

According to the U.S. National Institute of Health's Office of Dietary Supplements, sales of dietary supplements in the United States reached $21.3 billion in 2005. By category, vitamins provided $3.0 billion in sales, herbs $4.4 billion, minerals $1.8 billion, sports nutrition products $2.2 billion, multivitamins/minerals $4.2 billion, and other supplements totaling $5.7 billion.

Vitamins

Vitamins are micronutrients, or substances that the body uses in small amounts, as compared to macronutrients, which are the proteins, fats, and carbohydrates that make up most of food. Vitamins are present in food, but adequate quantities of vitamins may be reduced when food is overcooked, processed, or improperly stored. For instance, processing whole wheat grain into white flour reduces the contents of vitamins B and E, fiber, and minerals, including zinc and iron. The body requires vitamins to support its basic biochemical functions, and deficiencies over time can lead to serious disorders and have other negative health consequences.

Vitamins are either water-soluble or fat-soluble. Water-soluble vitamins dissolve in water and are not stored in the body, meaning that the body needs them on a regular basis. Water-soluble vitamins include the B-complex vitamins and vitamin C. Fat-soluble vitamins are stored in the body's fatty tissue, meaning that extra quantities can be stored for use by the body later. Fat-soluble vitamins include vitamins A, D, E, and K.

The amount of vitamins needed by the body has been the subject of much research. The U.S. government has published recommended dietary allowances (RDAs) for each vitamin for the general population. These figures can be used as guidelines, but individuals may have different needs depending on gender, age, activity level, and health conditions.

Vitamins can be natural or synthetic. Natural vitamins are extracted from food sources, while synthetic vitamins are formulated in laboratory processes. The only vitamin for which there is a noted difference between the natural and synthetic forms is **vitamin E**. The natural form is labeled d-alpha-tocopherol while the synthetic form is named dl-alpha-tocopherol, with the extra "l" signifying laboratory production. Natural vitamin E has been shown to be absorbed slightly more efficiently by the body than the synthetic version. For other vitamins no significant differences in absorption have been noted.

Minerals

Minerals are micronutrients and are essential for the proper functioning of the body. Cells in the body require minerals as part of their basic make-up and chemical balance, and minerals are present in all foods. Minerals can either be bulk minerals, used by the body in larger quantities, or trace minerals, used by the body in minute or trace amounts. Bulk minerals include **sodium**, potassium, **calcium**, magnesium, and phosphorus. Trace minerals include iron, zinc, selenium, iodine, chromium, copper, manganese, and others. Some studies have shown that the amount of minerals, particularly trace minerals, may be decreasing in foods due to mineral depletion of the soil caused by unsustainable farming practices and soil erosion. Supplemental minerals are available in chelated form, in which they are bonded to proteins in order to improve their absorption by the body.

Herbs

Herbal supplements may be added to the diet for both nutritional and medicinal purposes. Herbs have been used for centuries in many traditional medicine systems, and as sources of phytochemicals, or substances found in plants that have notable effects on the body. Chinese medicine and **Ayurvedic medicine** from India, two of the world's oldest healing systems, use hundreds of herbal medications. Naturopathy and homeopathy, two other systems of natural healing, also rely on herbal preparations as their main sources of medication. Some of the medicinal effects of herbs are getting scientific validation; about one-fourth of all pharmaceuticals have been derived directly from plant sources, including **aspirin** (found in willow bark); codeine (from poppy seeds); paclitaxel (Taxol), a patented drug for ovarian and **breast cancer** (from the Pacific yew tree); and many others.

Herbs can supplement the diet to aid in overall health or may be intended to stimulate healing for specific conditions. For instance, **ginseng** is often used to increase overall health and vitality, while **echinacea** is popularly believed to stimulate the body's resistance to colds and infections. Herbs come in many forms. They can be purchased as capsules and tablets, as well as in tinctures, teas, syrups, and ointments.

Meal supplements

Meal supplements are used to replace or fortify meals. They may be designed for people with special needs, or for people with illnesses that may affect digestion capabilities and nutritional requirements.

Meal supplements may contain specific blends of macronutrients, or proteins, carbohydrates, fats, and fiber. Some meal supplements consist of raw, unprocessed foods, or may be vegetarian or vegan, or have high protein and low fat composition. Meal supplements are available to support some popular diet programs. They are often fortified with vitamins, minerals, herbs, and nutrient-dense foods.

Sports nutrition

Nutritional supplements may be designed to provide specialized support for athletes. Some of these consist of high-protein products, such as amino acid supplements, while other products contain nutrients that support metabolism, energy, and athletic performance and recovery. People engaging in intense athletic activity may have increased needs for water-soluble vitamins, **antioxidants**, and certain minerals, including chromium. Sports drinks may contain blends of electrolytes (salts) that the body loses during exertion and sweating, as well as vitamins, minerals, and performance-supporting herbs.

Other nutritional supplements

Other nutritional supplements include nutrient-dense food products. Examples of these are brewer's yeast, spirulina (sea algea), bee pollen and royal jelly, fish oil and essential fatty acid supplements, colostrum (a specialty dairy product), psyllium seed husks (a source of fiber), wheat germ, wheatgrass, and medicinal mushrooms such as the shiitake and reishi varieties.

Specialty products may offer particular health benefits or are targeted for specific conditions. These products may consist of whole foods or may be isolated compounds from natural or synthetic sources. Examples include antioxidants, **probiotics** (supplements containing bacteria helpful to the digestion process), digestive enzymes, shark cartilage, other animal products, and chemical extracts such as the hormone DHEA (dehydroepiandrosterone) and coenzyme Q10, an antioxidant.

General guidelines

Considering average dietary needs and the prevalence of certain health conditions, some basic guidelines may provide the foundation for the effective use of nutritional supplements. First, a high quality, broad-spectrum multivitamin and mineral supplement, taken once per day, may be recommended for some people. This should contain the B-complex vitamins B_6, B_{12}, and **folic acid**, which may help prevent **heart disease**, and the minerals zinc and copper, which aid immunity. In addition to a multivitamin, antioxidants can be added to a supplementation routine. These include **vitamin A** (or beta-carotene), vitamin C, and vitamin E, and the mineral selenium. Antioxidants are popularly believed have several positive effects on the body, such as slowing the **aging** process, reducing the risks of cancer and heart disease, and reducing the risks of illness and infection by supporting the immune system. Coenzyme Q10 is another antioxidant in wide usage, as studies have shown it may improve the health of the heart and reduce the effects of heart disease. Essential fatty acids, particularly omega-3, are also recommended as they are involved in many important processes in the body, including brain function. Calcium supplementation is recommended for the elderly and for women, to support bone strength. Calcium supplements that are balanced with magnesium have a less constipating effect and are better absorbed.

After basic nutritional requirements are supported, supplements may be used to target specific needs and health conditions. For instance, athletes, men, women, children, the elderly, and vegetarians have differing needs for nutrients, and an informed use of supplements would take these differences into account. People suffering from health conditions and diseases may use specific supplements to target their condition and to support the body's healing capacity by providing optimal amounts of nutrients.

Recommended dosage

Dosages of nutritional supplements vary widely, depending on the product and individual needs. For vitamins and minerals, U.S. RDA's are general guidelines. For other products, manufacturers' guidelines, consumer information sources such as nutritional books and magazines, and practitioners including nutritionists and naturopathic physicians may be consulted.

Precautions

Nutritional supplements are not regulated by the FDA in the same way that prescription and over-the-counter drugs are. Instead, nutritional supplements are regulated in the same way as food. This means that makers of nutritional supplements do not have to prove the effectiveness of their products before putting them on the market. Nutritional supplements that make claims about the benefits of their product are required to carry a label stating that "This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease."

WWW.BOOKBAZ.IR

Because nutritional supplements are regulated in the same way as food products, the FDA may only take action against a product once it is already on the market. This means that sometimes products that are harmful, contaminated, or that make misleading claims can make onto retail shelves. In the past products have been identified by the FDA as containing more, or less, of the vitamin, mineral, or herb, than stated on the package, as contaminated with pesticides, heavy metals, or prescription drugs, as containing herbs not identified on the label, and as possibly causing dangerous interactions with prescription drugs. Because of these concerns it is extremely important that individuals **exercise** caution when making decisions about taking nutritional supplements.

Overall diet is an important first consideration for those considering nutritional supplementation. Healthy dietary habits can help optimize nutrition and the absorption of supplements, and nutritional supplements cannot substitute for a diet that is not nutritionally balanced. A good diet contain a variety of wholesome foods. The U.S. Department of Agriculture's MyPyramid food guide provides guidelines for a healthy diet, and can be found at www.MyPyramid.gov. Variety in the diet is important to provide a full range of vitamins and minerals. Overeating inhibits digestion and absorption of nutrients, while regular exercise contributes to sound nutrition, by improving metabolism and digestion. Drinking plenty of water prevents **dehydration**, improves digestion, and helps the body flush out impurities.

Generally, nutrients from food sources are more efficiently utilized by the body than isolated substances. For instance, fresh fruit and vegetable juice could be used to provide concentrated amounts of particular nutrients, such as vitamins A and C, to the diet. Eating plenty of leafy green vegetables is a healthy option for those wishing to add calcium to the diet.

Vitamins and minerals are most easily digested with food. Fat-soluble vitamins should be taken with food that contains fat. Vitamins tend to work synergistically, meaning that they work together in order to be effective. For instance, vitamin E requires some of the B-complex vitamins and the minerals selenium and zinc for most effective absorption. Some minerals may not be absorbed or may inhibit each other when taken in improper ratios. Generally, a high quality, broad-spectrum vitamin and mineral supplement is formulated to prevent unfavorable interactions.

Many vitamins, minerals, and herbs are toxic when taken in large quantities. Vitamin A can become toxic when taken in large amounts (more than 100,000 International Units), as can **vitamin D**. Substituting beta-carotene for vitamin A can alleviate this risk. Large doses of fat-soluble vitamins, because extra amounts of the vitamin are stored in the body, can have serious negative health consequences. Water-soluble vitamins are not stored in the body, and therefore extra quantities are excreted in the urine. Large doses of minerals, especially taken over time, may also have toxic effects in the body. Dosages far exceeding RDA's of vitamins are not recommended, nor are large doses of other supplements.

KEY TERMS

Antioxidants—A class of biochemicals that have been found to protect cells from free-radical damage.

Enzymes—Chemical catalysts that help initiate biochemical processes.

Essential fatty acids—Sources of fat in the diet, including omega-3 and omega-6 fatty acids.

Naturopathic physicians—Physicians specializing in the treatment of disease using a variety of natural methods and plant-based medicines.

Vitamins, minerals, and herbs may interact dangerously with prescription or over-the-counter medications, may make some medications less effective, or may cause some medical conditions to become worse. For example, St. John's wort can interfere with birth control medications, with medications used to treat cancer and HIV infection, and medications taken by organ transplant patients. Ginseng can cause lowered blood sugar levels, which can be dangerous when used in combination with some medications used to treat diabetes. It is extremely important that individuals talk with their doctor or pharmacist about how a nutritional supplement may interact with their medications and affect their health conditions before beginning to take it.

Consumers can make wise choices for nutritional supplementation by consulting a physician, pharmacist, nutritionist, or other health professionals. Nutritional supplements are best added into the diet slowly, starting with small dosages and working up to the manufacturers' recommended amounts over time. Also, some supplements, such as herbal medications that may stimulate processes in the body, are best taken intermittently, allowing the body occasional rest periods without the supplement. To avoid unfavorable interactions, nutritional supplements are best used moderately and individually, rather than taking handfuls of capsules and tablets

for various needs and conditions at the same time. Finally, consumers should be wary of excessive or grandiose health claims made by manufacturers of nutritional supplements and rely on scientific information to validate these claims.

Side effects

Some nutritional supplements can cause upset stomach and allergic reactions, including **rashes**, flushing, nausea, sweating, and headaches.

Interactions

Herbal preparations and nutritional supplements may interact unfavorably with pharmaceutical drugs. For instance, some nutritional supplements such as taking 5-HTP, a nutritional supplement for the brain, or the herb St. John's Wort, may not be recommended for those taking pharmaceutical antidepressants. Vitamin C should not be taken with aspirin, as it can irritate the stomach and limit absorption. Minerals should be taken in proper proportions to prevent unfavorable interactions; large amounts of zinc may deplete the body of the mineral copper, while too much calcium adversely affects the magnesium levels in the body. Balanced mineral supplements are recommended to alleviate these interactions.

Nystagmus

Definition

Rhythmic, oscillating motions of the eyes are called nystagmus. The to-and-fro motion is generally involuntary. Vertical nystagmus occurs much less frequently than horizontal nystagmus and is often, but not necessarily, a sign of serious brain damage. Nystagmus can be a normal physiological response or a result of a pathologic problem.

Description

The eyes play a critical role in maintaining balance. They are directly connected to other organs of equilibrium, most important of which is the inner ear. Paired structures called the semicircular canals deep in the skull behind the ears sense motion and relay that information to balance control centers in the brain. The eyes send visual information to the same centers. A third set of sensors consists of nerve endings all over the body, particularly in joints, that detect position. All this information is integrated to allow the body to navigate in space and gravity.

It is possible to fool this system or to overload it with information so that it malfunctions. A spinning ride at the amusement park is a good way to overload it with information. The system has adapted to the spinning, expects it to go on forever, and carries that momentum for some time after it is over. Nystagmus is the lingering adjustment of the eyes to tracking the world as it revolves around them.

Nystagmus can be classified depending upon the type of motion of the eyes. In pendular nystagmus the speed of motion of the eyes is the same in both directions. In jerk nystagmus there is a slow and fast phase. The eyes move slowly in one direction and then seem to jerk back in the other direction.

Nystagmus can be present at birth (congenital) or acquired later on in life. A certain type of acquired nystagmus, called spasmus nutans, includes a head tilt and head bobbing and generally occurs between four to 12 months of age. It may last a few months to a few years, but generally goes away by itself.

Railway nystagmus is a physiological type of nystagmus. It happens when someone is on a moving train (thus the term railway) and is watching a stationary object which appears to be going by. The eyes slowly follow the object and then quickly jerk back to start over. Railway nystagmus (also called optokinetic nystagmus) is a type of jerk nystagmus. This phenomenon can be used to check vision in infants. Nystagmus can also be induced by fooling the semicircular canals. Caloric stimulation refers to a medical method of testing their connections to the brain, and therefore to the eyes. Cold or warm water flushed into the ear canal will generate motion signals from the inner ear. The eyes will respond to this signal with nystagmus if the pathways are intact.

WWW.BOOKBAZ.IR

KEY TERMS

Binocular fixation—Both eyes pointed to and looking at the same object.

Cataract—A clouding of the lens of the eye.

Optic atrophy—Degeneration of the optic nerve.

Semicircular canals—Structures of the inner ear that help in maintaining balance.

Vertigo—A sense of spinning usually accompanied by unsteadiness and nausea.

Causes and symptoms

There are many causes of nystagmus. Nystagmus may be present at birth. It may be a result of the lack of development of normal binocular fixation early on in life. This can occur if there is a cataract at birth or a problem is some other part of the visual system. Some other conditions that nystagmus may be associated with include:

- Albinism. This condition is caused by a decrease in pigmentation and may affect the eyes.
- Disorders of the eyes. This may include optic atrophy, color blindness, very high nearsightedness (myopia) or severe astigmatism, or opacities in the structures of the eyes.
- Acute labyrinthitis. This is an inflammation in the inner ear. The patient may have dizziness (vertigo), nausea and vomiting, and nystagmus.
- Brain lesions. Disease in many parts of the brain can result in nystagmus.
- Alcohol and drugs. Alcohol and some medications (e.g., anti-epilepsy medications) can induce or exaggerate nystagmus.
- Multiple sclerosis. A disease of the central nervous system.

Diagnosis

Nystagmus is a sign, not a disease. If abnormal, it indicates a problem in one of the systems controlling it. An ophthalmologist and/or neuro-ophthalmologist should be consulted.

Treatment

There is one kind of nystagmus that seems to occur harmlessly by itself. The condition, benign positional vertigo, produces vertigo and nystagmus when the head is moved in certain directions. It can arise spontaneously or after a **concussion**. **Motion sickness** medicines sometimes help. But the reaction will dissipate if continuously evoked. Each morning a patient is asked to produce the symptom by moving his or her head around until it no longer happens. This prevents it from returning for several hours or the entire day.

Prisms, **contact lenses**, eyeglasses, or **eye muscle surgery** are some possible treatments. These therapies may reduce the nystagmus but may not alleviate it. Again, because nystagmus may be a symptom, it is important to determine the cause.

O

Obesity

Definition

Obesity, sometimes also called being excessively overweight, is an abnormal accumulation of body fat—usually 20% or more over an individual's ideal body weight. A person is considered overweight if one's **body mass index** (BMI) is between 25 and 29.9, and a person is considered obese if the BMI is over 30. Obesity can severely interfere with one's daily functions, and it is associated with increased risk of illness, disability, and even death.

The branch of medicine that deals with the study and treatment of obesity is known as bariatrics. As obesity has become a major health problem in the United States, bariatrics has become a separate medical and surgical specialty.

Description

Obesity is excessive body weight that develops over time as people consume more energy than they expend. As excess calories accumulate in the body, people first become overweight, then obese. The ability of the human body to store energy can mean the difference between life and death in times of famine. However, this protective mechanism becomes a potential problem when food is readily available in unlimited quantities. This is evident in the increasing prevalence of obesity in modern society, particularly in the developed world. As obesity rates have increased, bariatrics—the branch of medicine that studies and treats obesity—has become a separate medical and surgical specialty in developed countries.

The human body is composed of bone, muscle, specialized organ tissues, and fat. Together these comprise the total body mass, measured in pounds (lb) or kilograms (kg). Fat, or adipose tissue, is a combination of essential and storage fats. Essential fat is an energy source for the normal physiologic function of cells and organs. It is tucked in and around internal organs, and is an important building block for all cells of the body. Storage fat is a reserve supply of energy. It accumulates in the chest and abdomen and, in much greater volume, under the skin. When the amount of energy consumed as food exceeds the amount of energy expended in the maintenance of life processes and physical activity, storage fat accumulates in excessive amounts.

In the past, obesity was defined as body weight that was at least 20% above one's ideal weight. Ideal weight was defined as the weight at which individuals of the same height, gender, and age had the lowest rate of death. Mild obesity was defined as 20–40% over ideal weight, moderate obesity as 40–100% over ideal, and gross or morbid obesity 100% over ideal weight.

Current guidelines use the body mass index (BMI) to define obesity. The BMI utilizes height and weight to compare the ratio of body fat to total body mass. To calculate BMI using metric units, weight in kilograms is divided by height in meters squared. To calculate BMI in English units, weight in pounds is divided by height in inches squared and then multiplied by 703. This calculated BMI is compared to the statistical distribution of BMIs for adults aged 20–29 to determine whether an individual is underweight, average, overweight, or obese. The 20–29-year age group was chosen as the standard because it represents fully developed adults at the point in their lives when they have the least amount of body fat. Ideally, body fat is about 15% of total body mass for adult males and about 20–25% for adult females. However, BMI does not distinguish between fat and muscle.

Adult BMIs are age- and gender-independent. All adults aged 20 and older are evaluated on the same BMI scale as follows:

- underweight: BMI below 18.5
- normal weight: BMI 18.5–24.9

SOURCE: Doctors On-Line, Inc. "Height and Weight Goals as Determined by the Metropolitan Life Insurance Company."

(Table by PreMediaGlobal. © Cengage Learning®.)

- overweight: BMI 25.0–29.9
- obese: BMI 30 and above

Ranges are slightly different for Asian populations. Research has shown that the risk of developing type 2 diabetes and **heart disease** tends to be associated with lower BMIs in Asian populations than in European populations (on which the BMIs are based). Ranges vary, but generally the cap for normal weight is set at 22.9, and a BMI of 23 or higher is considered overweight.

The BMI for children and teens is calculated in the same way as for adults, but the results are interpreted differently. A child's BMI is compared to those of other children of the same age and gender and assigned to a percentile. For example, a girl in the 75th percentile for her age group weighs more than 74 of every 100 girls her age and less than 25 of every 100 girls her age. The percentiles indicate the following:

- underweight: below the 5th percentile
- healthy weight: 5th percentile to below the 85th percentile
- at risk of overweight: 85th percentile to below the 95th percentile
- overweight: 95th percentile and above

The CDC does not use the term "obese" for children and teens because the proportion of body fat fluctuates during growth and development and is slightly higher than in mature adults.

Obesity places **stress** on the body's organs and puts people at higher risk for many serious and potentially life-threatening health problems:

- fatigue
- joint problems
- poor physical fitness
- digestive disorders
- dizzy spells
- rashes
- sleep apnea
- mental health problems (depression)
- hypertension (high blood pressure)
- menstrual disorders
- complications during childbirth and surgery
- type 2 diabetes mellitus (non-insulin dependent)
- heart disease
- unexplained heart attack
- gallstones
- breathing problems
- hyperlipidemia (high level of fats in the blood)
- infertility
- colon, prostate, endometrial, and breast cancers
- premature aging

Obesity is estimated to reduce life expectancy by about seven years. Many diseases, especially degenerative diseases of the joints, heart, and blood vessels, tend to be more severe in obese individuals, increasing the need for some surgical procedures. Increasing prevalence of type 2 diabetes in the United States and the appearance of type 2 diabetes in children, previously a rarity, are directly related to an increased prevalence of obesity.

Body mass index (BMI) calculation and meaning

Body mass index is determined by a person's weight and height:

Pounds/inches		Kilograms/meters	BMI	Weight status
$\frac{\text{weight (lb)} \times 703}{[\text{height (in)}]^2}$	(or)	$\frac{\text{weight (kg)}}{[\text{height (m)}]^2}$	Below 18.5 18.5–24.9 25.0–29.9 30.0 and above	Underweight Normal Overweight Obese

(Table by PreMediaGlobal. © Cengage Learning®.)

Although acute complications of obesity are rare in children, **childhood obesity** is a risk factor for **insulin resistance** and type 2 diabetes, **hypertension**, hyperlipidemia, liver and renal disease, and reproductive dysfunction. Childhood obesity increases the risk of deformed bones in the legs and feet. It can also result in emotional disorders, such as depression caused by social **isolation** and negative comments by peers. Moreover, childhood obesity increases the risk of adult obesity and cardiovascular disease.

In 2011, the cost of obesity to the American economy was estimated at more than $100 billion, excluding dollars spent on commercial weight-loss programs. The increasing prevalence of obesity and diabetes in children and young adults heralds increased healthcare costs in the future. The social costs of obesity, including decreased productivity, discrimination, depression, and low self-esteem, are less easily measured.

In 1995, the Institute of Medicine of the U.S. National Academies published a report describing obesity as a "complex, multifactorial disease of appetite regulation and energy metabolism." The report cited the following outcomes from even relatively modest weight loss:

- lower blood pressure (and lower risk of heart attack and stroke)
- reduction of abnormally high levels of blood glucose
- lower blood levels of cholesterol and triglycerides (and lower risk of cardiovascular disease)
- lower incidence of sleep apnea
- lower risk for osteoarthritis in weight-bearing joints
- lower incidence of depression
- improved self-esteem

Risk factors

Obesity tends to run in families. Children of obese parents are about 13 times more likely than other children to be obese. Additional obese family members, including siblings and grandparents, greatly increase the likelihood of childhood obesity. The tendency toward a body type with an unusually high number of fat cells—termed *endomorphic*—appears to be inherited. Other genetic factors influence appetite and the metabolic rate at which food is transformed into energy. However, family eating habits are major contributors to the development of obesity. Although the majority of adopted children have patterns of weight gain that more closely resemble those of their birth parents than those of their adoptive parents, normal-weight children adopted into obese families are more likely than other children to become obese. Longitudinal studies of juvenile-onset obesity have demonstrated parental and peer encouragement of overeating and even deliberate overfeeding of obese children.

Low socioeconomic status is a risk factor for adult-onset obesity. A diet of high-fat, high-sugar refined food and a sedentary lifestyle are also risk factors.

Demographics

Obesity is a serious **public health** problem that affects both sexes and all ethnic, racial, age, and socioeconomic groups in the United States and around the world. According to the U.S. Centers for Disease Control and Prevention (CDC), about 31% of adult men and 35% of adult women (a total of about 100 million people) in the United States are obese, as well as 17% of children (aged 2–19). Obesity is the most common nutritional disorder among American children and teens.

The prevalence of obesity varies with age and ethnicity. According to the CDC, non-Hispanic blacks have the highest rate of obesity in the United States, with a rate of 44.1%, followed by Mexican Americans (39.3%), Hispanics (37.9%), and non-Hispanic whites (32.6%). The greatest rates of obesity were found in

WWW.BOOKBAZ.IR

the South and Midwest. With respect to socioeconomic status, non-Hispanic black men and Mexican American men with higher incomes were more likely to be obese than those with lower incomes. With respect to females, all women with higher incomes were less likely to be obese than lower-income women. In the United States, education backgrounds did not seem to affect obesity levels. Among children, African American and Hispanic children are considerably more likely to be overweight than Caucasian Americans.

The World Health Organization (WHO) recognizes obesity as a global problem. WHO estimated in 2011 that 1.5 billion people worldwide were overweight, of which 500 million were obese. The number of overweight children in Africa and Asia is increasing rapidly, while in the same countries other children are dying of complications of under- or **malnutrition**.

Causes and symptoms

Obesity is caused by the consumption of more energy than the body uses to drive physiological functions. The excess energy is stored as adipose tissue. Although inheritance may play a role, a genetic predisposition toward weight gain alone does not cause obesity. Hormonal and genetic disorders account for less than 10% of obesity in children. Eating habits, physical activity, and environmental, behavioral, social, and cultural factors all contribute to the development of obesity.

Nevertheless, sometimes obesity does have a purely physiological cause, as in the following:

- Cushing's syndrome, a disorder involving the excessive release of the hormone cortisol
- hypothyroidism caused by an underactive thyroid gland, resulting in low levels of the hormone thyroxin and the slow metabolism of food, causing excess unburned calories to be stored as fat
- neurological disturbances, such as damage to the hypothalamus, a structure located deep within the brain that helps regulate appetite
- certain drugs, such as steroids, antipsychotic medications, and antidepressants

Some researchers have suggested that low levels of the neurotransmitter serotonin increase cravings for carbohydrates. In addition, a combination of genetics and early nutritional habits may result in a higher "set point" for body weight that causes obese individuals to feel hunger more often than others. Recent obesity research has focused on two peptide hormones, leptin and ghrelin. Leptin, produced by fat cells, affects hunger and eating behavior; insensitivity to leptin may contribute to obesity. Ghrelin is secreted by cells in the lining of the stomach and is important in appetite regulation and maintaining the body's energy balance.

However, most obesity is caused by simple overeating. During past decades, American eating habits have changed significantly, with many people consuming larger meals and more high-calorie processed foods. School and workplace cafeterias often have a poor selection of nutritional food offerings. Food is sold in many venues besides restaurants and supermarkets. Furthermore, it is estimated that in a given six-month period, 2–5% of Americans binge eat. It has been estimated that approximately 15% of the mildly obese participating in weight-loss programs have **binge eating disorder** and that the percentage is much higher among the morbidly obese. Current evidence indicates that weight gain depends primarily on total calories consumed, rather than the source of calories being from carbohydrates, protein fats or alcohol, and that low-fat **diets** are no more effective for weight reduction than other low-calorie diets. Different approaches work better for different individuals depending on lifestyle habits and dietary preferences.

Sedentary lifestyles, which are particularly prevalent among affluent socioeconomic groups, also contribute to obesity. Rather than physical labor on farms and in factories, many people are now employed in sedentary jobs in post-industrial service industries. Energy-saving machines and devices—cars, remote control devices, household electric appliances, and power tools—have become standard equipment. One study found that the average Western European adult walks about 8,000–9,000 steps daily. In contrast, among the Amish of Pennsylvania who do not use cars or electricity, men accumulate 18,425 steps daily and have no obesity. Amish women walk 14,196 steps daily and have an obesity rate of only 9%.

Psychological factors, such as depression and low self-esteem, can contribute to overeating and obesity. People may eat compulsively to overcome fear or social maladjustment, express defiance, or avoid intimate relationships.

Some babies are born large for their gestational age. This can be caused by excessive insulin production in the fetuses of diabetic mothers, excessive transplacental nutrients in the case of obese mothers, or excessive weight gain during **pregnancy**.

Some babies become obese because they are overfed. Families may value a plump baby, or caregivers may use a bottle to quiet an infant or to demonstrate their own

KEY TERMS

Adipose tissue—Fat tissue.

Anemia—Red blood cell deficiency.

Appetite suppressant—A drug that reduces appetite.

Bariatrics—The branch of medicine that deals with the prevention and treatment of obesity and related disorders.

Binge eating disorder—A condition characterized by uncontrolled eating.

Body mass index (BMI)—A measure of body fat: the ratio of weight in kilograms to the square of height in meters.

Calorie—A unit of food energy.

Carbohydrate—Sugars, starches, celluloses, and gums that are a major source of calories from foods.

Catecholamines—Hormones and neurotransmitters including dopamine, epinephrine, and norepinephrine.

Eating disorder—A condition characterized by an abnormal attitude towards food, altered appetite control, and unhealthy eating habits that affect health and the ability to function normally.

Epidemic—Affecting many individuals in a community or population and spreading rapidly.

Fat—Molecules composed of fatty acids and glycerol; the slowest utilized source of energy, but the most energy-efficient form of food. Each gram of fat supplies about nine calories, more than twice that supplied by the same amount of proteins or carbohydrates.

Gastroplasty—A surgical procedure used to reduce digestive capacity by shortening the small intestine or shrinking the side of the stomach.

Ghrelin—A peptide hormone secreted primarily by the stomach that has been implicated in the control of food intake and fat storage.

Hyperlipidemia—Abnormally high levels of lipids in the blood.

Hyperplastic obesity—Excessive weight gain in childhood, characterized by an increase in the number of fat cells.

Hypertension—Abnormally high arterial blood pressure, which if left untreated can lead to heart disease and stroke.

Hypertrophic obesity—Excessive weight gain in adulthood, characterized by expansion of pre-existing fat cells.

Ideal weight—Weight corresponding to the lowest death rate for individuals of a specific height, gender, and age.

Leptin—A peptide hormone produced by fat cells that acts on the hypothalamus to suppress appetite and burn stored fat.

Metabolic activity—The sum of the chemical processes in the body that are necessary to maintain life.

Metabolic bone disease—Weakening of bones due to a deficiency of certain minerals, especially calcium.

Normal weight—A BMI of less than 25.0.

Obesity—An abnormal accumulation of body fat, usually 20% or more above ideal body weight or a BMI of 30.0 or above.

Off-label use—Drugs in the United States are approved by the Food and Drug Administration (FDA) for specific uses, periods of time, or dosages based on the results of clinical trials. However, it is legal for physicians to administer these drugs for other "off-label" or non-approved uses. It is not legal for pharmaceutical companies to advertise drugs for off-label uses.

Osteoporosis—A disease characterized by low bone mass and structural deterioration of bone tissue, leading to bone fragility.

Overweight—A BMI between 25.0 and 30.0.

Serotonin—A neurotransmitter located primarily in the brain, blood serum, and stomach membrane.

competence as caregivers. Because obese one-year-olds may be physically delayed in crawling and walking, they become less active toddlers, burning fewer calories. By the age of 10, obese boys and girls are taller than their peers by as much as 4 inches (10 cm). Their skeletal maturation, called bone-age, is also accelerated, so they stop growing earlier. Sexual maturation is advanced. It is not uncommon for obese girls to experience early onset of menstruation, sometimes even before the age of 10. Parental separation and divorce or other psychological stresses may stimulate compensatory overeating in children. Obese teenagers and, increasingly, obese preteens may combine periods of binge eating and caloric deprivation, leading to bulimia or **anorexia nervosa**.

In developed countries, people generally experience increased BMI with age. The proportion of intra-abdominal fat, which correlates with disease and

WWW.BOOKBAZ.IR

death, increases progressively with age. There is also a progressive decline in daily total energy expenditure, associated with decreased physical activity and lower metabolic activity, especially in those with chronic disabilities and diseases.

The major symptoms of obesity are excessive weight and large amounts of fatty tissue. Common secondary symptoms include **shortness of breath** and lower back **pain** from carrying excessive body weight. Obesity can also give rise to secondary conditions including:

- arthritis and other orthopedic problems
- hernias
- heartburn
- adult-onset asthma
- gum disease
- high cholesterol levels
- gallstones
- high blood pressure
- menstrual irregularities or cessation of menstruation (amenorrhea)
- decreased fertility and pregnancy complications
- incapacitating shortness of breath
- sleep apnea and sleeping disorders
- skin disorders from the bacterial breakdown of sweat and cellular material in thick folds of skin or from increased friction between folds
- emotional and social difficulties

Diagnosis

Examination

Obesity is usually diagnosed by observation of excessive storage fat and by calculating BMI from weight and height. Physicians also observe how the excess weight is carried by comparing waist and hip measurements: "apple-shaped" patients—who store most of their weight around the waist and abdomen—are at greater risk for cancer, heart disease, **stroke**, and diabetes than "pear-shaped" patients whose extra pounds settle primarily in their hips and thighs.

Procedures

BMIs and other measurements do not necessarily accurately reflect body composition and muscle mass. A heavily muscled football player may weigh far more than a sedentary man of similar height, but have significantly less body fat. Chronic dieters, who have lost significant muscle mass during periods of caloric deprivation, may look slim and weigh little but have elevated body fat. Therefore direct measurements of body fat are obtained using calipers to measure skinfold thickness at the back of the upper arm and other sites, which distinguishes between muscle and adipose tissue.

The most accurate means of estimating body fat is hydrostatic weighing—calculating the volume of water displaced by the body. The patient exhales as completely as possible and is immersed in water and the relative displacement is measured. Women whose body fat exceeds 30–32% of total body mass by this method and men whose body fat exceeds 25–27%, are generally considered obese. Since this method is unpleasant and impractical, it is usually used only in scientific studies.

Treatment

Treatment of obesity aims at reducing weight to a BMI within the normal range (below 25.0). The best way to achieve weight loss is to reduce dietary caloric intake and increase physical activity. However, obesity will return unless the weight loss includes life-long behavioral changes. "Yo-yo" dieting, in which weight is repeatedly lost and regained, has been shown to increase the likelihood of fatal health problems even more than no weight loss at all.

Behavioral treatment for obesity is goal-directed and process-oriented and relies heavily on self-monitoring, with emphasis on:

- Food intake. This may involve keeping a food diary and learning the nutritional value, caloric content, and fat content of foods. It may involve changing shopping habits, such as only shopping on a certain day and buying only what is on the grocery list, timing meals and planning frequent small meals to prevent hunger pangs, and eating slowly to allow for satiation.
- Response to food. This may involve understanding psychological issues underlying eating habits. For example, some people binge eat when under stress, whereas others use food as a reward. By recognizing psychological triggers, alternate coping mechanisms that do not focus on food can be developed.
- Time management. Integrating exercise into everyday life is a key to achieving and maintaining weight loss. Starting slowly and building endurance helps to keep patients from becoming discouraged. Varying routines and trying new activities helps to keep interest high.
- Stimulus control. This may involve removing environmental cues for inappropriate eating.

- Contingency management. A system of positive and negative reinforcements may help with behavioral modification.

Most mildly obese individuals can make these lifestyle changes independently with medical supervision. Others may utilize a commercial weight-loss program, such as Weight Watchers. The effectiveness of these programs is difficult to assess, since they vary widely, dropout rates are high, and few employ medical professionals. However, programs that emphasize realistic goals, gradual progress, sensible eating, and **exercise** can be very helpful and are recommended by many physicians. Programs that promise instant weight loss or utilize severely restricted diets are not effective and, in some cases, can be dangerous.

Moderately obese individuals require medically supervised behavior modification and weight loss. A realistic goal is a 10% weight loss over a six-month period. Most doctors use a balanced, low-calorie diet of 1,200–1,500 calories a day. However, sometimes certain patients may be put on a medically supervised very low 400–700-calorie liquid protein diet, with supplementation of **vitamins** and **minerals**, for as long as three months. This therapy should not be confused with commercial liquid-protein diets or weight-loss shakes and drinks. Very-low-calorie diets must be designed for specific patients who are monitored carefully and are used for only short periods. Physicians will also refer patients to professional therapists or psychiatrists for help in changing eating behaviors. Without changing eating habits and exercise patterns, the lost weight will be regained quickly.

For morbidly obese individuals, dietary changes and behavior modification may be accompanied by **bariatric surgery**. Gastroplasty involves inserting staples to decrease the size of the stomach. Gastric banding is an inflatable band inserted around the upper stomach to create a small pouch and narrow passage into the remainder of the stomach. Bariatric surgery has become less risky in recent years due to innovations in equipment and surgical techniques. However, it is still performed only on patients for whom supervised diet and exercise strategies have failed, who are at least 100 lb (45 kg) overweight or twice their ideal body weight, and whose obesity seriously threatens their health. Risks and possible complications include infections, hernias, and **blood clots**. Overall, 10–20% of patients who undergo weight-loss surgery require additional operations to correct complications, more than 33% develop **gallstones**, and 30% develop nutritional deficiencies, such as anemia, **osteoporosis**, or metabolic bone disease.

Other bariatric surgical procedures—including **liposuction**, a purely cosmetic procedure in which a suction device removes fat from beneath the skin, and **jaw wiring**, which can damage gums and teeth and cause painful muscle spasms—have no place in obesity treatment.

Weight loss is recommended for obese children over age seven and for obese children over age two who have medical complications. Weight maintenance is an appropriate goal for children over the age of two who have no medical complications. Most treatment approaches to childhood obesity involve a combination of caloric restriction, physical exercise, and behavioral therapy. Bariatric surgery is considered as a last resort only for adolescents who are fully grown.

Drugs

The short-term use of prescription medications may assist some individuals in managing their condition, but it is never the sole treatment for obesity, nor are drugs ever considered as a cure for obesity. Diet drugs are designed to help medically at-risk obese patients "jump-start" their weight-loss effort and lose 10% or more of their starting body weight, in combination with a diet and exercise regimen. Prescription weight-loss drugs are approved by the U.S. Food and Drug Administration (FDA) only for patients with a BMI of 30 or above, or a BMI of 27 or above and an obesity-related condition, such as high blood pressure, type 2 diabetes, or dyslipidemia (abnormal amounts of fats in the blood). The weight is usually regained as soon as the drugs are discontinued, unless eating and exercise habits have changed.

Most appetite-suppressants are based on amphetamine. They increase levels of serotonin or catecholamine, brain chemicals that control feelings of fullness. Serotonin also regulates mood and may be linked to mood-related eating behaviors. Prescription weight-loss medications include:

- benzphetamine hydrochloride (Didrex)
- diethylpropion (Tenuate, Tenuate Dospan)
- mazindol (Mazanor, Sanorex)
- phendimetrazine (Bontril, Melfiat)
- phentermine (Adipex-P, Ionamin)
- lorcaserin hydrochloride (Belviq)
- phentermine and topiramate (Qsymia)

While most of the immediate side effects of appetite suppressants are harmless, their long-term effects may be unknown. Dexfenfluramine hydrochloride (Redux), fenfluramine (Pondimin), and the fenfluramine-phentermine combination (Fen-Phen) were taken off the

WWW.BOOKBAZ.IR

market after they were shown to cause potentially fatal cardiac effects. Sibutramine (Meridia) was known to significantly elevate blood pressure and was taken off the market in 2010. Phenylpropanolamine, a component of many nonprescription weight-loss and cold and **cough** medications (Acutrim, Dex-A-Diet, Dexatrim, Phenldrine, Phenoxine, PPA, Propagest, Rhindecon, Unitrol) was removed from shelves because of an increased risk of stroke. Appetite suppressants can be habit-forming and have the potential for abuse. Appetite suppressants should not be used by patients taking **monoamine oxidase inhibitors** (MAOIs) and are not recommended for children.

Side effects of prescription and over-the-counter weight-loss products may include:

- constipation
- dry mouth
- headache
- irritability
- nausea
- nervousness
- sweating

Unlike appetite suppressants, orlistat is a lipase inhibitor that reduces the breakdown and absorption of dietary fat in the intestines. Both its prescription (Xenical) and nonprescription (Alli) forms are approved by the FDA. Orlistat is intended to be used with a calorie-controlled diet and exercise program. Side effects may include abdominal cramping, gas, fecal urgency, oily stools, frequent bowel movements, and **diarrhea**.

Other drugs are sometimes prescribed off-label for treating obesity. For example, fluoxetine (Prozac) is an antidepressant that sometimes aids in temporary weight loss. Side effects of this medication include diarrhea, **fatigue**, **insomnia**, nausea, and thirst.

Alternatives

Functional food diets are newer, as yet unproven, approaches to weight loss:

- carbohydrates with a low glycemic index, which may help suppress appetite
- high fiber supplements
- green tea extract, which may increase the body's energy expenditure
- chromium, which may encourage the burning of stored fat rather than lean muscle tissue

Various herbs and supplements are promoted for weight loss:

- Diuretic herbs, which increase urine production, can result in short-term weight loss, but do not help with lasting weight control. Increased urine output increases thirst to replace lost fluids, and patients who use diuretics for an extended period of time eventually start retaining water anyway.
- In moderate doses, psyllium, a mucilaginous herb available in bulk-forming laxatives like Metamucil, absorbs fluid and provides a feeling of fullness.
- The amino acid 5-hydroxytryptophan (5-HTP), which is extracted from the seeds of *Griffonia simplicifolia*, is thought to increase serotonin levels in the brain. Patients should consult with their healthcare provider before taking 5-HTP, as it may interact with other medications and can have potentially serious side effects.

Acupressure and **acupuncture** can suppress food cravings. Visualization and **meditation** can create and reinforce a positive self-image that can enhance a patient's determination to lose weight. By improving physical strength, mental concentration, and emotional serenity, **yoga** can provide the same benefits. Patients who play soft slow music during meals often find that they eat less food, but enjoy it more.

Eating a reasonable balance of protein, carbohydrates, and high-quality fats are important for weight loss. Support and self-help groups—such as Overeaters Anonymous and TOPS (Taking Off Pounds Sensibly)—that promote nutritious, balanced diets can help patients maintain proper eating regimens. Many diet support groups also exist on the Internet.

Fad dieting can have harmful health effects. Weight should be lost gradually and steadily by decreasing calories while maintaining an adequate nutrient intake and level of physical activity. A daily caloric intake of 1,000–1,200 calories for women and 1,200–1,600 for men enables most people to lose weight safely. A loss of about 2 lb (1 kg) per week is recommended, which means burning on average around 500 calories per day. Diets of less than 800 calories a day should never be attempted unless prescribed and monitored by a physician.

At least 60–90 minutes of daily moderate-intensity physical activity is usually recommended to maintain weight loss. Obese people who have led sedentary lives may need monitoring to avoid injury as they begin to increase their physical activity. Exercise should be increased gradually, perhaps starting by climbing stairs instead of taking elevators, followed by walking, biking, or swimming at a slow pace. Eventually 15-minute walks can be built up to brisk 45–60-minute walks.

The American Academy of Family Physicians offers advice for families with children who need to maintain or lose weight:

- Weight-loss interventions should begin as soon as possible in children over two years of age.
- The family must be ready for change; if not, the program is likely to fail.
- The physician should educate the family as to the medical complications of obesity.
- All family members and caregivers should be involved in the treatment program.
- The physician should encourage the child and family, not criticize them.
- The treatment program should institute permanent changes in eating habits and other behaviors.
- The program should help the family to make small gradual changes.
- The program should include learning ways to monitor eating and exercise.
- Goals should be realistic; even a 5% weight loss, if maintained, can reduce risks to health.

Prognosis

The primary factor in achieving and maintaining weight loss is a life-long commitment to sensible eating habits and regular exercise. As many as 85% of dieters who do not exercise on a regular basis regain their lost weight within two years and 90% regain it within five years. Short-term diet programs and repeatedly losing and regaining weight encourage the storage of fat and may increase the risk of heart disease.

However, prudent dieting and exercise are not quick cures for obesity. With decreased caloric intake, the body breaks down muscle for carbohydrates. Much of the early weight loss on a very low-calorie diet represents loss of muscle tissue rather than fat. Similarly, fat is not easily accessed as fuel for exercise.

The chronically or habitually obese tend to come from families with a larger number of risk factors for obesity and have a much more difficult time losing weight than the newly obese. Likewise, previously obese people have a high probability of reverting to obesity.

When obesity develops in childhood, the total number of fat cells increases (hyperplastic obesity), whereas in adulthood the total amount of fat in each cell increases (hypertrophic obesity). Patients who were obese as children may have up to five times as many fat cells as a patient who became obese as an adult. Decreasing the amount of energy (food) consumed or increasing the amount of energy expended reduces the amount of fat in the cells—but does not reduce the number of fat cells already present—and this process is slow, just like the accumulation of excess fat.

Neonatal obesity does not necessarily translate into childhood or adult obesity, but there is an increased probability if the child is born or adopted into a family with multiple obese members. Likewise, excess weight in a child under the age of three does not necessarily predict adult obesity unless one of the parents is obese.

Summer camps specializing in habitually obese children, especially girls, have little long-term success in reducing obesity and a high degree of recidivism for habitual overeating and under-exercising. About 30% of overweight girls eventually develop **eating disorders**.

According to the Obesity Prevention Center at the University of Minnesota, obesity-control programs that rely on educational messages encouraging greater physical activity and a healthier diet have been only modestly successful. The best outcomes have been with children's programs that have high levels of physical activity.

Prevention

Prevention is far superior to any available treatment for obesity. Obesity can be prevented by eating a healthy diet, being physically active, and making lifestyle changes that help maintain a normal weight. Examples include

- eating smaller portions of food
- taking the time to prepare healthy meals
- avoiding processed foods
- parking farther away from a store
- walking or bicycling instead of driving
- walking the dog instead of just letting it out

Obesity experts suggest that monitoring fat consumption, as well as counting calories, is a key to preventing excess weight gain. The National **Cholesterol** Education Program of the National Heart, Lung, and Blood Institute maintains that only 30% of calories should be derived from fat and only one-third of those should be saturated fats. High concentrations of saturated fats are found in meat, poultry, and dairy products. Fat replacers or substitutes are now added to many foods. They reduce the amount of fat and usually also reduce the number of calories. It is not clear what effect these will have on the long-term battle against obesity.

However, total caloric intake cannot be ignored, since it is usually the slow accumulation of excess calories, regardless of the source, that results in obesity. A single daily cookie providing 25 excess calories will result in a 5 lb (2.3 kg) weight gain by the end of one year.

WWW.BOOKBAZ.IR

Because most people eat more than they think they do, keeping a detailed and honest food diary is a useful way to assess eating habits. Eating three balanced, moderate-portion meals a day—with the main meal at mid-day—is a more effective way to prevent obesity than **fasting** or crash diets that trick the body into believing it is starving. After 12 hours without food, the body has depleted its stores of readily available energy and begins to protect itself for the long term. Metabolic rate starts to slow and muscle tissue is broken down for the raw materials needed for energy maintenance.

The U.S. Department of Agriculture (USDA) food plate, called *MyPlate* to distinguish it from the replaced food pyramid, contains recommendations on diet and exercise based on the *Dietary Guidelines for Americans 2010*, tailored for an individual's BMI. It includes recommendations on physical activity and in five food categories: grains, vegetables, fruits, dairy, and proteins.

It has been suggested that there may be little benefit in encouraging weight loss in older people, especially when there are no obesity-related complications or when promoting changes in lifelong eating habits creates stress. However, studies have shown that weight loss in seniors can lower the incidence of arthritis, diabetes, and other conditions, reduce cardiovascular risk factors, and improve well being. Increased physical activity in the elderly also improves muscle strength and endurance.

The poor prognosis for reversing adult obesity makes childhood prevention imperative. Unhealthy eating patterns and behaviors associated with obesity can be addressed by programs in **nutrition**, exercise, and stress management involving the entire family.

Obesity and surgery

Definition

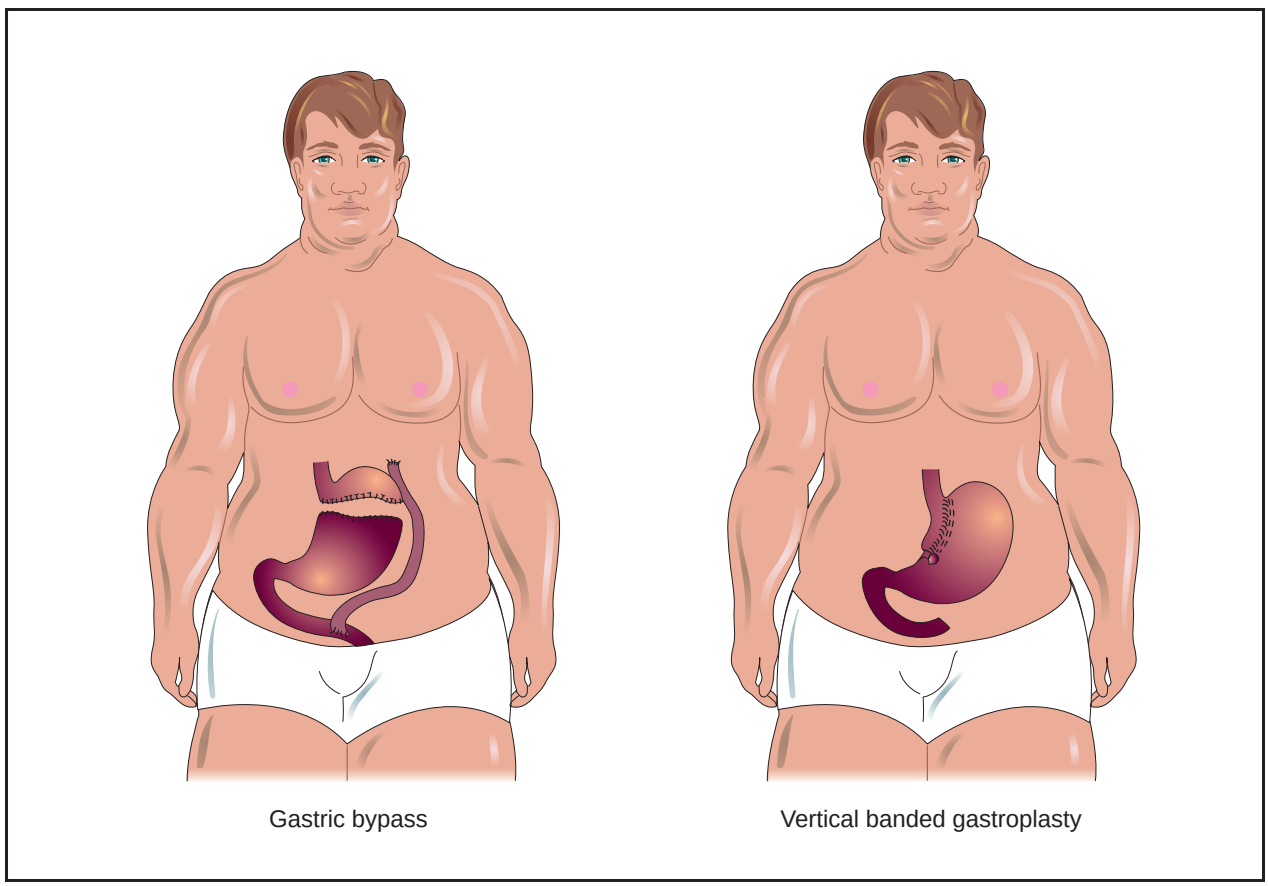
Obesity increases the risk for various chronic conditions, such as diabetes and **heart disease**, that can lead to complications requiring surgery. Obesity may also increase the risk of complications during and after surgery. On the other hand, being overweight or obese appears to improve outcomes for some surgeries—a phenomenon called the "obesity paradox."

Demographics

Obesity is a growing worldwide epidemic. An estimated 35% of adults and almost 17% of children and adolescents in the United States are obese. These percentages have been steadily increasing—in 2001, only 15% of adults were considered obese. As a result of this increase, the number of obese patients undergoing nonbariatric as well as bariatric (weight-loss) surgeries is increasing. Conditions associated with obesity—such as type 2 diabetes, obstructive **sleep apnea**, high blood pressure, and cardiovascular disease—may complicate **anesthesia** and surgery.

Description

Obesity is an excessive accumulation of fat that is usually defined by having a **body mass index** (BMI)



The purpose of obesity surgery is to reduce the size of the stomach and slow the stomach emptying process by narrowing the entrance into the intestine. With this surgery, the volume of food the stomach can hold is reduced from approximately 4 cups to approximately one-half cup. There are two types of procedures used for obesity surgery: gastric bypass and vertical banded gastroplasty, as shown in the illustration above. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

WWW.BOOKBAZ.IR

equal to or greater than 30. Because obesity increases morbidity and mortality, it is generally viewed as a risk factor for poor surgical outcomes and complications. Surgery on patients with severe or morbid obesity is of particular concern. Morbid or severe obesity, defined as having a BMI of 40 or above, affects 3–4% of the general population and is the fastest growing segment of the obese population.

Excess fat is primarily deposited subcutaneously (under the skin) and viscerally (in the abdomen). Abdominal fat appears to account for much of the increase in obesity and is associated with metabolic syndrome (MS). However, although about two-thirds of people with MS are obese, some obese people are metabolically healthy. Some researchers believe that it is MS that is primarily responsible for obesity-related conditions—such as diabetes, cardiovascular disease, and certain types of cancer—and that subcutaneous fat may be protective. They postulate that it is excess visceral fat and MS—rather than BMI—that affect postoperative immune system function and morbidity and mortality associated with surgery. They suggest that waist circumference and waist-to-height or waist-to-hip ratios, which assess abdominal obesity, may be more important than BMI for predicting surgical risks and complications.

Surgery on obese patients, particularly severely obese patients, usually takes longer with more loss of blood. Because the field of operation is deeper, the operation is more difficult and there is a higher risk of wound complications or infection. Obesity poses special challenges for anesthesiologists, as well, and routine monitoring during surgery can be difficult. Veins can be harder to locate, and medication dosing can vary. It may even be difficult to find a blood pressure cuff that fits the patient's arm. Airway management can be challenging due to obesity-related changes in anatomy. Obstructive sleep apnea can interfere with airflow and oxygen uptake with even minimal amounts of **sedation**. Intubation (placement of a breathing tube) may require special equipment and techniques.

Obesity is by far the most common risk factor for surgical site infection (SSI) and hospital readmission. Since SSI and readmission rates are considered primary measures of surgical quality, some researchers argue that surgeons and hospitals, especially those that treat high-obesity populations, are unfairly penalized by government and insurance company "pay for performance" policies. Furthermore, some surgeons and hospitals may avoid treating obese patients because they entail longer and more complex surgeries for equal or lower payments.

Specific surgeries

Obesity increases the risk of colorectal cancer—the fourth most common cancer in the United States and the third leading cause of cancer deaths. In Europe, being overweight or obese has been estimated to increase the risk of **colon cancer** in men by 30–70%, with the risk increasing with each incremental increase in BMI. However, the risk appears to be primarily associated with abdominal rather than subcutaneous fat. Obesity may also be associated with worse outcomes, including cancer recurrence and death, but it does not appear to have a significant impact on colorectal cancer surgery except for a greater risk of SSI. A 2011 study found that obesity increased the SSI risk in patients undergoing colectomy by 60%. SSI added $17,000 to the cost of surgery, increased the average hospital stay by more than a day, and caused a 27.8% rate of hospital readmissions compared to 6.8% for non-obese patients. Patients with SSIs also had a delay in return to daily activities and an increased risk of long-term complications.

Among other surgeries:

- A 2012 study found that lobectomy for primary lung cancer took an additional 7.2 minutes for every 10-unit increase in BMI, even at hospitals experienced in treating obese patients. However, obesity did not increase 30-day mortality rates or the length of hospital stay.
- A 2012 study found that obesity was associated with disease recurrence and poorer survival in women with hormone-receptor-positive operable breast cancer but not with other types of breast cancer.
- A 2011 study found that obese patients undergoing elective plastic surgery, primarily breast reductions, were 12 times more likely to have postsurgical complications. Obese patients were 22 times more likely to have inflammation, 13 times more likely to contract infections, and 11 times more likely to suffer pain.

Transplantation

Obesity is increasingly common both before and after **liver transplantation**. Chronic **liver disease** has traditionally been accompanied by anorexia and wasting, and pre-transplant **nutrition** is used to maintain or increase body weight. However, obesity appears to be either the primary cause or a contributing factor for end-stage liver disease. Although in the medium term, liver transplant outcomes are similar for obese and

non-obese patients, over the long term, obese patients have much poorer outcomes, including recurrence of hepatitis and morbidity and mortality from diabetes, heart disease, and cancer. A 2012 study found that obesity was an independent risk factor for portal vein thrombosis in liver transplant patients.

Obesity among would-be organ donors is also a growing concern. Although the risks faced by obese donors are not well understood, there is concern that **organ donation** may potentially endanger their health. The percentage of obese kidney donors rose from about 14% in 2000 to almost 20% in 2008, with about 2% having BMIs over 35. Just over half of transplant centers cap donor BMI at 35, and about 10% cap it at 30. At a time when more than 92,000 Americans are awaiting a kidney transplant, this excludes a significant number of potential donors. Although obese donors are at higher risk for minor surgical complications, major complications remain rare. The larger concern is that obesity raises the risk of **kidney disease**. However, it is unclear whether the risk of kidney failure is greater with just one kidney. Normal-weight donors have a similar or even reduced risk of kidney failure compared with the general population. Obese liver donors—both deceased donors and living donors who part with a portion of their liver—are also of concern, since they often have non-alcoholic **fatty liver** disease, which poses a risk for both the donor and the recipient.

Preparation

Obese patients should consult with their physician about their condition and options and whether a particular surgery is safe for them. Technical difficulties and the risk of complications should be explained. Because recovery can be more difficult for obese patients, they should be as healthy as possible before surgery. Patients should discuss the advisability of proceeding with a weight-loss program or procedure prior to surgery. Patients with diabetes should have their blood sugar well controlled.

Presurgical testing includes a physical exam, cardiovascular and respiratory history, and recording height, weight, and BMI. An electrocardiogram, **chest x ray**, **exercise** testing, and other noninvasive procedures may be performed. However, evaluation of severely obese patients may be difficult. For example, a complaint of chest tightness could be an obesity symptom or indicate underlying heart problems, which are often underestimated in severely obese patients. The patient's age, gender, and cardiorespiratory condition, as well as any history of or risk for **electrolyte disorders** or **heart failure**, should each be considered as an independent factor for surgical complications or death. Researchers have proposed developing obesity risk scoring tools for specific surgeries, as are sometimes used for weight-loss surgery risks. The anesthesiologist should explain specific risks associated with obesity and anesthesia. Induction of anesthesia and preparation for surgery usually take longer than for normal-weight patients.

The hospital and department should have specific protocols and guidelines for caring for obese patients. Hospital staff should be trained in appropriate manual handling. Operating tables, trolleys, and beds should be labeled with their maximum weight capability. Special hospital beds should be available for obese patients.

Children

The American Society of Anesthesiologists has a program for educating parents about the increased risk of complications from anesthesia in obese children. Children's developing airways are prone to collapse under anesthesia, and obesity increases this risk. Obese children have extra tissue around the airway, chest, and abdomen that can interfere with breathing under anesthesia and restrict oxygen supply, leading to complications including impaired lung function or brain damage. Even minor weight loss before surgery may improve the outcome, but parents should check with their doctor and anesthesiologist to ensure that any weight-loss program does not interfere with the surgery. Parents should encourage healthy eating and exercise both before and after surgery.

Obese children can be particularly difficult to evaluate for appendectomies. Physical examinations can be complicated, inflammatory markers in the blood may be hard to interpret, and the appendix can be difficult to detect on **ultrasound**.

Aftercare

Following surgery, severely obese patients are likely to require breathing assistance with a ventilator for longer periods, in addition to longer hospital stays.

Results

Surgical results in obese patients vary greatly depending on the patient and the surgery, and newer techniques are improving results:

- A 2013 study found that obese patients had poorer outcomes and more dissatisfaction following surgery for lumbar spinal stenosis (narrowing of the lower

WWW.BOOKBAZ.IR

spinal column), although they did experience significant reduction in pain, improved walking ability, and better quality of life.

- A 2011 Mayo Clinic study found that obesity doubled the risk of esophageal cancer recurrence and death within five years of surgery.
- A 2013 study found that proximal rectal tumors could be safely treated by transanal endoscopic microsurgery in morbidly obese patients for whom transabdominal pelvic surgery often has a poor outcome.
- Obesity was associated with more frequent minor—but not major—complications immediately after transcatheter aortic valve implantation. However, obesity was also associated with a lower risk of 30-day mortality and had no effect on mortality after discharge.
- Percutaneous (through the skin) heart procedures have been reported to have better outcomes in obese patients than in patients of normal weight.

Morbidity and mortality rates

The association between obesity and morbidity and mortality following surgery remains unclear. Some studies have found that obese patients are at a much higher risk for potentially deadly surgical complications. In addition to SSI, they have been found to have a significantly higher risk for postoperative **heart attack**, nerve injury, and urinary tract infections. Morbidly obese patients—those more than 100 lb. (45 kg) over their ideal weight—were almost twice as likely to die of complications following non-cardiac surgeries than non-obese patients, although there was no difference in overall death rates between non-obese patients and those who were obese but not morbidly obese. Morbid obesity was also found to be independently associated with an increased risk of death after elective surgery. Obesity in children undergoing **appendectomy** is associated with higher morbidity and longer hospital stays, although outcomes are better with **minimally invasive surgery** compared to open surgery.

In contrast, other studies have found that obese patients—even the seriously obese—are no more likely than others to die as a result of surgery. Overweight and obese patients have better survival after heart valve surgery than patients with normal BMIs. A higher BMI is also associated with higher survival in patients undergoing **angioplasty** for **coronary artery disease**. Obese patients do not have higher postoperative mortality following coronary artery bypass surgery and appear to have a lower risk of repeat surgery for bleeding, although they have a higher risk of SSI. One study found that overweight and obese patients have a reduced risk of death in intensive care units. This data may be skewed, however, by the severely malnourished patients in the comparator group, who have markedly worse outcomes. Obesity is a risk factor for many of the conditions which require surgery, and in general results in higher complication rates.

KEY TERMS

Angioplasty—Opening up of a constricted blood vessel.

Atherosclerosis—Thickening and hardening of the inner layer of arteries due to the accumulation of plaque.

Bariatric surgery—Surgery to treat obesity.

Body mass index (BMI)—A measure of body fat, determined by the ratio of weight in kilograms to the square of height in meters.

Electrocardiogram (ECG, EKG)—A recording of the electrical impulses produced with each heartbeat.

Intubation—The insertion of an endotracheal tube to supply oxygen to the lungs and heart during anesthesia.

Metabolic syndrome (MS)—The presence of three or more factors—such as high blood pressure, abdominal obesity, high triglyceride levels, low "good" cholesterol levels, or high fasting blood sugar—that are linked to a risk for type 2 diabetes and cardiovascular disease.

Obesity paradox—The observation that, although obesity is usually linked to risk factors for various diseases and surgical complications, it sometimes appears to have a protective effect.

Obstructive sleep apnea—Recurrent interruption of breathing during sleep due to obstruction of the upper airway.

Pulmonary embolism—A blood clot that travels to the pulmonary artery, usually from a vein in the leg or pelvis.

Stenosis—The narrowing or constriction of a passageway or orifice, such as the spinal column.

Surgical site infection (SSI)—An infection that originates at the site in the body that was operated upon.

Thromboembolism—A blood clot that can break free and block a blood vessel elsewhere in the body.

Risks

Obesity may or may not be a risk factor for SSI, poor wound healing, and pulmonary and venous thromboembolisms (**blood clots**). However, conditions associated with obesity—including atherosclerosis, high blood pressure, heart rhythm disorders, heart failure, poor exercise capacity, **pulmonary hypertension** related to sleep apnea, and a history of blood clots, especially pulmonary embolism—increase risks to the heart during surgery. Anesthesia risks include airway and ventilation problems, nausea, and difficulty being lifted or moved. Severely obese patients are at increased risk of **pulmonary embolism**, wound infection, and wound failure during open surgery. Other risks include difficulty performing the surgery, bleeding, and organ damage. Obesity in children is associated with physiological changes that may adversely affect their response to surgery.

Alternatives

Obese patients can sometimes avoid surgery by weight loss alone or by substituting other treatments. Minimally invasive surgeries often have better outcomes than open surgeries in obese patients.

Obsessive-compulsive disorder

Definition

Obsessive-compulsive disorder (OCD) is classified as an **anxiety** disorder marked by the recurrence of intrusive or disturbing thoughts, impulses, images, or ideas (obsessions) accompanied by repeated attempts to suppress these thoughts through the performance of certain irrational and ritualistic behaviors or mental acts (compulsions). The obsessions and compulsions take up large amounts of the patient's time (an hour or longer every day) and usually cause significant emotional distress for the patient and difficulties in patient's relationships with others.

OCD should not be confused with obsessive-compulsive personality disorder even though the two disorders have similar names. Obsessive-compulsive personality disorder is not characterized by the presence of obsessions and compulsions; rather, it is a lifelong pattern of insistence on control, orderliness, and perfection that begins no later than the early adult years. It is possible, however, for a person to have both disorders.

Description

OCD is sometimes described as a malfunction of the brain's information processing system. Everyone has upsetting thoughts or impulses from time to time—such as the urge to shout dirty words in public or thinking about hitting someone—but most people are able to let go of these things and not worry about them. A person with OCD, however, gets stuck on the thoughts or impulses and cannot put them aside. These thoughts or impulses are called obsessions. Individuals who have them may think that they are going crazy or will not be able to keep from acting on the thoughts. To cope with the anxiety, these individuals engage in repetitive behaviors or mental acts to undo, counteract, or control the obsessions. These behaviors are called compulsions.

Common obsessions include fears of contamination by germs or dirt; fear that one has harmed someone; thoughts of violence or of killing a pet or family member; worrying about thoughts that violate one's religious beliefs; and fear of performing sexual acts that the person dislikes. Common compulsions include repeated hand washing or bathing; checking doors or car windows over and over to be sure they are locked; counting objects; insisting that personal possessions like clothes in a closet or items on a desk be arranged a particular way; touching objects in a specific sequence; and hoarding items that are not needed.

It is important to recognize that people with OCD are distressed by these behaviors and usually realize that they do not make sense. Compulsions may consume several hours of these persons' day, interfering with work, school, family life, and other activities. They can also be harmful to health; there are instances of people damaging their skin by frequent hand washing or taking long showers. Unlike people with substance abuse or **eating disorders**, people with OCD do not find their rituals pleasurable or satisfying; they are done only to manage their fears.

Studies of families with OCD members indicate that the particular expression of OCD symptoms may be affected by the responses of other people. Families with a high level of tolerance for the symptoms are more likely to have members with more extreme or elaborate symptoms. Problems often occur when the OCD member's obsessions and rituals begin to control the entire family. For example, other family members may find themselves running late for appointments because the OCD member insists on completing their obsessional ritual before they will get in the car.

Risk factors

Known risk factors for OCD include:

- a family history of OCD
- a history of head trauma
- being diagnosed with Tourette syndrome or attention deficit hyperactivity disorder (ADHD)
- a high level of intelligence and education
- higher socioeconomic status
- a pre-existing anxiety disorder, particularly PTSD, phobias, or social anxiety disorder
- high levels of long-term environmental stress

Demographics

Although descriptions of patients with OCD have been reported since the fifteenth century in religious and medical literature, the condition was widely assumed to

be rare until the late twentieth century. Epidemiological research beginning in 1980 identified OCD as the fourth most common psychiatric illness, after **phobias**, substance use disorders, and major **depressive disorders**. As of 2014, OCD was present classified as a form of anxiety disorder, but some studies indicated that it results from a combination of psychological, neurobiological, genetic, and environmental causes.

According to some estimates, as of 2014, one adult in every 50 in North America had OCD, and two out of 50 have had it at some point in their lives. According to the International OCD foundation, 2–3 million adults in the United States have OCD. It is likely, however, that the disorder is underdiagnosed because many people who suffer from it are embarrassed by their symptoms and often skilled at hiding them from others.

OCD can begin at any age, including childhood; in fact, between one-third and one-half of adults diagnosed with the disorder say that their symptoms began in childhood. The most common age for the emergence of symptoms is between ten and 24 years, with slightly more women than men being diagnosed with OCD. Childhood OCD is more common in males, and the sex ratio does not favor females until adulthood. People with OCD appear to be less likely to marry than persons diagnosed with other types of mental disorders.

OCD is equally common in all races and ethnic groups in the United States, although patients' specific obsessions are sometimes influenced by their cultural background. For example, fears of violating religious practices or beliefs are reported to be more common among Roman Catholics and Orthodox Jews than among Protestants. Worldwide, cross-cultural studies of OCD indicate that while the incidence of the disorder seems to be about the same in most countries, the symptoms are often shaped by the patients' culture of origin. For example, a patient from a Western country may have a contamination obsession that is focused on germs, whereas a patient from India may fear contamination by touching a person from a lower social caste.

Both males and females can develop OCD; however, males are more likely to begin showing symptoms in childhood and adolescence, and females are more likely to develop symptoms in their early twenties.

Causes and symptoms

There are various causes and symptoms for obsessive-compulsive disorder.

Causes

At one time it was thought that OCD was caused by childrearing practices that made individuals anxious. Such compulsions as repeated washing or checking door locks were explained as rituals intended to please parents who were overly concerned with cleanliness or safety. In the early part of the twentieth century, Sigmund Freud theorized that OCD symptoms were caused by punitive, rigid toilet-training that led to internalized conflicts. This type of psychological explanation fell out of favor later in the century.

There are several subsequent theories about the possible causes of OCD:

- Genetic: It is known that having other family members with OCD increases a person's risk of developing the disorder. Childhood-onset OCD appears to run in families more than adult-onset OCD and is more likely to be associated with tic disorders. Twin studies indicate that monozygotic, or identical twins, are more likely to share the disorder than dizygotic, or fraternal twins. The concordance (match) rate between identical twins is not 100%, however, which suggests that the occurrence of OCD is affected by environmental as well as genetic factors. In addition, it is the general nature of OCD that seems to run in families rather than the specific symptoms; thus, one family member who is affected by the disorder may have a compulsion about washing and cleaning while another is a compulsive counter. Although two genes have been linked to OCD, one discovered in 1994 and the other in 2007, researchers had not as of 2014 been able to prove that either or both cause the disorder.
- Abnormally low levels of serotonin in the brain: Serotonin is a chemical produced by the brain that regulates mood, appetite, sleep, and memory. Serotonin affects the efficiency of communication between the front part of the brain (the cortex) and structures that lie deeper in the brain known as the basal ganglia. Dysfunction in the serotonergic system occurs in certain other mental illnesses, including major depression. OCD appears to have a number of features in common with the so-called obsessive-compulsive spectrum disorders, which include Tourette syndrome, Sydenham's chorea, eating disorders, trichotillomania, and delusional disorders. One piece of evidence that supports the serotonin theory is that patients with OCD who are given a type of antidepressant that makes more serotonin available to brain cells obtain some relief from their symptoms. These antidepressants are called selective serotonin reuptake inhibitors, or SSRIs.

- Differences in brain structure: Researchers who have used magnetic resonance imaging (MRI) to map the regions of the brain have found that patients diagnosed with OCD have significantly less white matter in their brains than do normal control subjects. Other studies using positron emission tomography (PET) scanning indicate that OCD patients have patterns of brain activity that differ from those of people without mental illness or with some other mental illness. These findings suggest that there is a widely distributed brain abnormality in OCD.
- Infections: OCD in children has sometimes been attributed to a complication of strep throat. This theory holds that the affected child's body produces antibodies against the strep throat bacteria. The disorder was sometimes referred to as pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS). It was thought that antibodies in the child's blood cross-react with structures in the basal ganglia, producing or worsening the symptoms of OCD or tic disorders. However, in the early 2000s this theory was no longer as widely accepted as it was in the 1990s; it was controversial and considered unproven.

Symptoms

The symptoms of OCD should not be confused with the ability to focus on detail or to check one's work that is sometimes labeled compulsive in everyday life. This type of attentiveness is an important factor in academic achievement and in doing well in such fields that require close attention to detail as accounting, medicine, or engineering. By contrast, the symptoms of OCD are serious enough to interfere with the person's daily functioning. Historical examples of OCD include the medieval Englishman William of Oseney, who spent twelve hours per day reading religious books in order to be at peace with God, and Freud's Rat Man, a patient who had repeated dreams of cursing Freud and covering him with dung. While the Rat Man was ashamed of these impulses and had no explanation for them, he could not control them.

More recent accounts of OCD symptoms include those of a young man who compulsively touched every electrical outlet as he passed, washed his hands several times an hour, and returned home repeatedly to check that the doors and windows were locked. Another account described a firefighter who was worried that he had throat cancer. He spent three hours a day examining his throat in the mirror, feeling his lymph nodes, and asking his wife if his throat appeared normal.

More common obsessions and compulsions are described below.

CONTAMINATION. People with contamination obsessions are usually preoccupied with a fear of dirt or germs. They may avoid leaving home or allowing visitors to come inside in order to prevent contact with dirt or germs. Some people with contamination obsessions may wear gloves, coats, or even masks if they are forced to leave their house for some reason. Obsessions with contamination may also include abnormal fears of such environmental toxins as lead, asbestos, or radon.

Washing compulsions are commonly associated with contamination obsessions. For example, a person concerned about contamination from the outside may shower and launder all clothing immediately upon coming home. The compulsion may be triggered by direct contact with the feared object but, in many cases, even being in its general vicinity may stir up intense anxiety and a strong need to engage in a washing compulsion. The late Howard Hughes exhibited this kind of washing compulsion; he would even burn his clothing after finding out that he had been in the same room with a sick person. Another man who was afraid of contamination could not take even a short walk down the street without experiencing a compulsion to disinfect the soles of his shoes, launder all his clothing, and wash his hands until they were raw after he returned to his apartment.

Washing compulsions may not always be caused by a fear of germs. That is, a need for perfection or for symmetry may also lead to unnecessary washing. In such cases, the individual may be concerned about being perfectly clean or feel that he cannot leave the shower until his left foot has been washed exactly as many times as his right foot. Other people with washing compulsions may be unable to tolerate feeling sweaty or otherwise not clean.

OBSESSIONAL DOUBTING. Obsessional doubting refers to the fear of having failed to perform some task adequately and that dire consequences will follow as a result. Although individuals with this symptom may try to suppress the worrisome thoughts or images, they usually experience a rising anxiety which then leads to a compulsion to check the task. For example, they may worry about forgetting to lock the door or turn off the gas burner on the stove and spend hours checking these things before leaving home. In one instance, a man was unable to throw away old grocery bags because he feared he might have left something valuable inside one of them. Immediately after looking into an empty bag, he would again wonder if he missed something in the bag. In many cases, no amount of checking is sufficient to dispel the maddening sense of doubt.

NEED FOR SYMMETRY. Persons suffering from an obsession about symmetry often report feeling acutely uncomfortable unless they perform certain tasks in a symmetrical or balanced manner. Thus, crossing one's legs to the right must be followed by crossing legs to the left; scratching one side of the head must be followed by scratching the other; tapping the wall with a knuckle on the right hand must be followed by tapping with one on the left, and so on. Sometimes the person may have a thought or idea associated with the compulsion, such as a fear that a loved one will be harmed if the action is not balanced, but often there is no clearly defined fear, only a strong sense of unease.

AGGRESSIVE AND SEXUAL OBSESSIONS. Aggressive and sexual obsessions are often particularly horrifying to those who experience them. For some people, obsessive fears of committing a terrible act in the future compete with fears that they may already have done something awful in the past. Compulsions to constantly check and confess cause such individuals to admit to evildoing in which they had no part, a phenomenon familiar to law enforcement following highly publicized crimes. These obsessions often involve violent or graphic imagery that is upsetting and disgusting to the person, such as rape, physical assault, or even murder. One case study concerned a young woman who constantly checked the news to reassure herself that she had not murdered anyone that day; she felt deeply upset by unsolved murder cases. A middle-aged man repeatedly confessed to having molested a woman at work, despite no evidence of such an action ever occurring in his workplace.

SYMPTOMS IN CHILDREN. Obsessions and compulsions in children are often focused on germs and fears of contamination. Other common obsessions include fears of harm coming to self or others, fears of causing harm to another person, obsessions about symmetry, and excessive moralizing or religiosity. Global warming is an increasingly common focus of such obsessive moralizing in the twenty-first century.

Childhood compulsions frequently include washing, repeating, checking, touching, counting, ordering, and arranging. Younger children are less likely to have full-blown anxiety-producing obsessions, but they often report a sense of relief or strong satisfaction (a just-right feeling) from completing certain ritualized behaviors. Since children are particularly skillful in disguising their OCD symptoms from adults, they may effectively hide their disorder from parents and teachers for years.

Unusual behaviors in children that may be signs of OCD include:

- Avoidance of scissors or other sharp objects. A child may be obsessed with fears of hurting herself or others.
- Chronic lateness or dawdling. The child may be performing checking rituals (e.g., repeatedly making sure all her school supplies are in her bookbag).
- Daydreaming or preoccupation. The child may be counting or performing balancing rituals mentally.
- Spending long periods of time in the bathroom. The child may have a handwashing compulsion.

KEY TERMS

Basal ganglia—A group of masses of gray matter located in the cerebral hemispheres of the brain that control movement as well as some aspects of emotion and cognition.

Behavioral therapy—An approach to treatment that focuses on extinguishing undesirable behavior and replacing it with desired behavior.

Cognitive-behavioral therapy (CBT)—An approach to psychotherapy that emphasizes the correction of distorted thinking patterns and changing one's behaviors accordingly.

Compulsion—A repeated behavior or mental act carried out to control or neutralize obsessions.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Obsession—A recurrent, distressing, intrusive thought, image, or impulse.

Selective serotonin reuptake inhibitors (SSRIs)—A group of antidepressants that works by increasing the amount of serotonin available to nerve cells in the brain.

Serotonin—A brain chemical that influences mood, anger, anxiety, body temperature, and appetite.

Sydenham's chorea—A serious manifestation of acute rheumatic fever that commonly occurs in children ages seven through 14, peaking at age eight. This disease of the central nervous system is characterized by emotional instability, purposeless movements, and muscular weakness.

Tic—A sudden involuntary behavior that is difficult or impossible for the person to suppress. Tics may be either motor (related to movement) or vocal, and may become more pronounced under stress.

Trichotillomania—A disorder marked by repeated pulling and tugging of one's hair, usually resulting in noticeable hair loss on the scalp or elsewhere on the body.

WWW.BOOKBAZ.IR

- Schoolwork handed in late or papers with holes erased in them. The child may be repeatedly checking and correcting her work.

For both children and adults, the symptoms of OCD wax and wane in severity; the specific content of obsessions and compulsions may change over time. The disorder, however, very seldom goes away by itself without treatment. People with OCD in all age groups typically find that their symptoms worsen during major life changes or following highly stressful events.

Diagnosis

The diagnosis of OCD is often delayed because patients are often ashamed of their symptoms and skilled at hiding them. It has been estimated that it takes an average of 17 years from the time that a patient's symptoms begin for that person to be diagnosed correctly and receive treatment for OCD. Another reason for the delay is that a person with OCD often has other disorders, including substance abuse disorders, **bipolar disorder**, **panic disorder**, or depression, and the OCD symptoms may be attributed to the other disorders. In children, OCD is sometimes misdiagnosed as **autism** or **Tourette syndrome**.

The diagnosis of OCD may also be complicated because of the number of other conditions that resemble it. For example, major depression may be associated with self-perceptions of being guilty, bad, or worthless, which are excessive and unreasonable. Similarly, eating disorders often include bizarre thoughts about size and weight, ritualized eating habits, or the hoarding of food. Delusional disorders may entail unusual beliefs or behaviors, as do such other mental disorders as trichotillomania, **hypochondriasis**, the paraphilias, and substance use disorders. Thus, accurate diagnosis of OCD depends on the careful analysis of many variables to determine whether the apparent obsessions and compulsions might be better accounted for by some other disorder or to the direct effects of a substance or a medical condition.

In addition, OCD may coexist with other mental disorders, most commonly depression. It has been estimated that about 34% of patients diagnosed with OCD are depressed at the time of diagnosis and that 65% are likely to develop depression at some point in their lives.

Examination

Persons who are thought to have OCD are given a complete mental status examination. They are evaluated for memory, disturbances of mood and emotions, the presence of **hallucinations** or **delusions**, the risk of **suicide** or homicide, and judgment (whether the persons have insight into their symptoms). They should also be evaluated for the presence of Tourette syndrome or other tic disorders, as these comorbid diagnoses may influence treatment decisions.

The presence of hair loss, **eczema**, or scabs or scratches on the skin caused by compulsive washing, trichotillomania, or picking at the skin may be additional evidence for the diagnosis of OCD. There may not, however, be any physical evidence of the disorder.

Tests

There are no laboratory tests for OCD. The primary care doctor will refer the patient to a psychiatrist or psychologist for a specialized interview. The diagnosis is based on a combination of the patient's symptom history and their answers to a diagnostic questionnaire. The questionnaire most often used is the Yale-Brown Obsessive Compulsive Scale (Y-BOCS). The Y-BOCS has ten items, five for obsessions and five for compulsions. The questions evaluate the time consumed by symptoms, the extent to which they interfere with functioning, how much they distress the patient, and what the patient has done to try to control the symptoms.

Treatment

There are various treatments for obsessive-compulsive disorder.

Treatment for OCD is usually based on a combination of medications and **psychotherapy**.

PSYCHOTHERAPY. Behavioral treatments using the technique of exposure and response prevention (ERP; sometimes called exposure and ritual prevention) are particularly effective in treating OCD. In this form of therapy, the patient and therapist draw up a list, or hierarchy, of the patient's obsessive and compulsive symptoms. The symptoms are arranged in order from least to most upsetting. The patient is then systematically exposed to the anxiety-producing thoughts or behaviors, beginning with the least upsetting. The patient is asked to endure the feared event or image without engaging in the compulsion normally used to lower anxiety. For example, persons with a contamination obsession might be asked to touch a series of increasingly dirty objects without washing their hands. In this way, the patients learn to tolerate the feared object, reducing both worrisome obsessions and anxiety-reducing compulsions. About 75–80% of patients

respond well to exposure and response prevention, with very significant reductions in symptoms.

Other types of psychotherapy have met with mixed results. Psychodynamic psychotherapy is helpful to some patients who are concerned about the relationships between their upbringing and the specific features of their OCD symptoms. Cognitive-behavioral psychotherapy may be valuable in helping patients to become more comfortable with the prospect of exposure and prevention treatments, as well as helping to identify the role that the patients' particular symptoms may play in their own life and what effects family members may have on the maintenance and continuation of OCD symptoms. Cognitive-behavioral psychotherapy is not intended to replace exposure and response prevention but may be a helpful addition to it. The combination of medication and CBT has been shown to be a particularly helpful form of therapy for OCD.

SURGERY. A very small number of patients with severe OCD that does not respond to medications or ERP are treated surgically. The surgeon makes a small cut in a part of the brain called the cingulate bundle. This technique produces significant benefits for about 30% of patients who receive the operation. It is considered a treatment of last resort for OCD.

Researchers study the effectiveness of newer drugs in treating OCD as well as deep brain stimulation or DBS. In DBS, thin wires are implanted in the parts of the brain that have been linked to OCD symptoms. A battery-powered stimulator sends electrical pulses to the brain at regular intervals in order to interfere with the activity of the nerve cells in the target areas. DBS has been used to treat Parkinson's disease and is considered an experimental treatment for Tourette syndrome.

Drugs

The medications usually prescribed to treat OCD are the **selective serotonin reuptake inhibitors** or SSRIs. These drugs work by increasing the amount of serotonin available to some of the nerve endings in the brain. Some patients also benefit from the tricyclic antidepressant clomipramine.

It is important, however, to know that the SSRIs must be prescribed with care in treating children and adolescents with OCD. Young patients and adults up to age 24 taking antidepressants for major depressive disorder have been found to be at increased risk for developing suicidal thoughts and actions. The risk appears to be reduced in patients taking SSRIs for OCD, but all patients taking SSRIs should be monitored for changes in behavior or worsening depression. An estimated 15% of persons with OCD make at least one suicide attempt.

Alternatives

Because OCD sometimes responds to selective serotonin reuptake inhibitors (SSRI) antidepressants, herbalists believe a botanical medicine St. John's wort (*Hypericum perforatum*) might have some beneficial effect as well. Known popularly as Nature's Prozac, St. John's wort is prescribed by herbalists for the treatment of anxiety and depression. They believe that this herb affects brain levels of serotonin in the same way that SSRI antidepressants do. Herbalists recommend a dose of 300 mg, three times per day. In about one out of 400 people, St. John's wort (like Prozac) may initially increase the level of anxiety. Homeopathic constitutional therapy can help rebalance the patient's mental, emotional, and physical wellbeing, allowing the behaviors of OCD to abate over time.

Other alternative treatments for OCD are intended to lower the patient's anxiety level; some are thought to diminish the compulsions themselves. Alternative recommendations include the following:

- Bach flower remedies, such as white chestnut for obsessive thoughts and repetitive thinking
- Traditional Chinese medicine (TCM), specifically a mixture of bupleurum and dong quai, to strengthen the spleen and regulate the liver. (In TCM, obsessive-compulsive disorder is explained as liver stagnation and a weak spleen.)
- Aromatherapy; a mixture of lavender, rosemary, and valerian is thought to promote relaxation.
- Yoga; yogis in India developed a special technique of yogic breathing specifically for OCD. The specific yogic technique for treating OCD requires blocking the right nostril with the tip of the thumb; slow deep inspiration through the left nostril; holding the breath; and slow complete expiration through the left nostril. This is followed by a long breath-holding out period.
- Schuessler tissue salts; for OCD, specific doses of *Ferrum phosphorica* and tablets of *Kali phosphorica* are recommended daily.
- Massage therapy, with special emphasis on loosening the muscles in the neck, back, and shoulders.

Prognosis

The prognosis of OCD varies from person to person. The disorder rarely goes away on its own. Few OCD patients become completely symptom-free, but

WWW.BOOKBAZ.IR

about 70% of patients benefit from treatment; however, symptoms may increase and decrease in a cyclical pattern over time. About 15% of patients get steadily worse over time even with treatment and may eventually become unable to function.

Prevention

There is no known way to prevent OCD; however, early diagnosis and prompt treatment can help to prevent the patient's symptoms from getting worse.

Obstetric and gynecologic surgery

Definition

Obstetric and gynecologic surgery refers to procedures that are performed to treat conditions affecting the female reproductive organs. The main structures of the reproductive system are the vagina, the uterus, the ovaries, and the fallopian tubes.

Description

Obstetrics is the branch of medicine that focuses on women during **pregnancy**, **childbirth**, and the postpartum period. Gynecology is a broader field, focusing on the general healthcare of women and treating conditions that affect the female reproductive organs. Medical doctors who choose to specialize in obstetrics and gynecology must undergo at least four years of post-medical school training (called a residency) in the areas of women's general health, pregnancy, labor and delivery, preconception and postpartum care, prenatal testing, and genetics. Obstetrician-gynecologists (also called OB-GYNs) may also subspecialize in the areas of gynecologic oncology (the treatment of cancers that affect the reproductive system), maternal-fetal medicine (the care of high-risk pregnancies), reproductive endocrinology and **infertility** (the study and treatment of the reproductive glands and hormones and the causes of infertility), and urogynecology (treatment of urinary tract and pelvic disorders).

Surgical procedures

A wide range of surgical procedures have been developed to treat the various conditions that affect the female reproductive organs.

THE VAGINA. The vagina is the muscular canal that extends from the opening of the vulva (the external female genitals) to the cervix or lower part of the uterus. The vagina is the outlet for menstrual blood and is where the penis is inserted during sexual intercourse.

Some common surgical procedures that are performed on the vagina include:

- Episiotomy. A surgical incision made in the perineum (the area between the vagina and anus) to expand the opening of the vagina to prevent tearing during delivery.
- Colporrhaphy. Surgical repair of the vagina may be necessary after childbirth, sexual assault, or other injuries.

- Colpotomy. This incision into the wall of the vagina may be used to excise ovarian cysts, perform tubal ligation, or remove uterine fibroids.
- Egg retrieval. This is a procedure used to extract the eggs from the ovaries prior to in vitro fertilization. A needle is placed through the vaginal wall to extract the eggs from the ovaries under ultrasound guidance.
- Colposcopy. A colposcope is a specialized instrument used to visualize the vagina and cervix, to diagnose abnormalities, or to test for the presence of precancerous or cancerous cells. In a colposcopy, a sample of potentially abnormal cells is taken for examination by a pathologist under a microscope.

THE UTERUS. The uterus is the hollow, muscular organ at the top of the vagina. The cervix is the neck-shaped opening at the lower part of the uterus, while the fundus is the rounded upper portion. The endometrium is the inner lining of the uterus. It is where a fertilized egg will implant during the early days of pregnancy. The endometrium normally sheds during each menstrual cycle if the egg released during ovulation has not been fertilized. The myometrium is the middle muscular layer of the uterus; it is the myometrium that rhythmically contracts during labor contractions.

Some common surgical procedures that are performed on the uterus include:

- Myomectomy. A procedure in which myomas (uterine fibroids) are surgically removed from the uterus.
- Cesarean section. A surgical procedure in which incisions are made through the woman's abdomen and uterus to deliver her baby.
- Cervical cerclage. The cervix is stitched closed to prevent a miscarriage or premature birth.
- Cervical cryosurgery. Cryosurgery freezes and destroys an area of the cervix in which precancerous cells have been found.
- Induced abortion. The intentional termination of a pregnancy before the fetus can live independently.
- Hysterectomy. The removal of part or the entire uterus may be done to treat uterine cancer, fibroid tumors, endometriosis, uterine prolapse, or other conditions of the uterus.
- Hysterotomy. This incision into the uterus is done during a cesarean section, open fetal surgery, and some second-trimester abortions.
- Dilatation and curettage. D&C is a gynecological procedure in which the cervix is dilated (expanded) and the lining of the uterus (endometrium) is scraped away.

THE OVARIES. The ovaries are egg-shaped structures located to each side of the uterus. The female egg develops within the ovaries. A mature egg is released from one of the ovaries approximately every 28 days during a process called ovulation.

The surgical procedures that are performed on the ovaries include:

- Oophorectomy. One or both ovaries may be removed during this procedure to prevent or treat ovarian or other cancers, to remove large ovarian cysts, or to treat endometriosis.
- Cystectomy. An ovarian cystectomy may be used to remove part of an ovary to treat ovarian tumors or cysts.

THE FALLOPIAN TUBES. The fallopian tubes are the structures that carry a mature egg from the ovaries to the uterus. These tubes, which are about 4 in. (10 cm) long and 0.2 in. (0.5 cm) in diameter, are found on the upper outer sides of the uterus, and open into the uterus through small channels. It is within a fallopian tube that fertilization, the joining of the egg and the sperm, takes place.

Some common surgical procedures that are performed on the fallopian tubes include:

- Salpingostomy. An incision is made in the fallopian tube, often to excise an ectopic pregnancy.
- Salpingectomy. One or both fallopian tubes are removed in this procedure. The procedure may be used to treat ruptured or bleeding fallopian tubes (as a result of ectopic pregnancy), infection, or cancer.
- Tubal ligation. A permanent form of birth control in which a woman's fallopian tubes are surgically cut or blocked off to prevent pregnancy.

THE VULVA. The external female genital organs (or vulva) include the labia majora, two lips or folds that enclose the labia minora. The labia minora, in turn, are two lips or folds that enclose the clitoris, a small sensitive organ with a high number of nerve endings.

Some examples of surgeries that affect the vulva are:

- Vulvectomy. The vulva may be partially or completely removed, as in the case of vulvar cancer.
- Laceration or hematoma repair. Vulvar hematoma (a localized collection of blood) or laceration may result from a "straddle" injury, sexual assault, or childbirth. Severe hematomas may need surgical drainage.

Obstetric and gynecologic anesthesia

Various options are available to women for **pain** relief during obstetric or gynecologic surgery. Pain medications given intravenously (into a vein) or intramuscularly (into a muscle) help to decrease the amount of

WWW.BOOKBAZ.IR

KEY TERMS

Ectopic pregnancy—A pregnancy that occurs outside of the uterus, most often in the fallopian tubes.

Endometriosis—A condition in which the endometrium (lining of the uterus) grows in places in the body outside of the uterus.

Ovarian cysts—Fluid-filled cavities on the surface of the ovary that may cause pain and bleeding if they become too large.

Uterine fibroids—Also called leiomyomas; benign growths in the smooth muscle of the uterus.

Uterine prolapse—A condition in which the uterus descends into or beyond the vagina.

pain during childbirth or certain procedures, although they will generally not completely eliminate pain.

Regional **anesthesia**, either a spinal or an epidural, is the preferred method of pain relief during childbirth and certain surgical procedures such as **cesarean section**, **tubal ligation**, cervical cerclage, and others that do not require the patient to be unconscious. The benefits of regional anesthesia include allowing the patient to be awake during the surgery, avoiding the risks of general anesthesia, and allowing early contact between mother and child in the case of a cesarean section.

Spinal anesthesia involves inserting a needle into a region between the vertebrae of the lower back and injecting numbing medications. An epidural is similar to a spinal except that a catheter is inserted so that numbing medications may be administered as needed. Some women experience a drop in blood pressure when a regional anesthetic is administered. This can be countered with fluids and/or medications.

In some instances, general anesthesia may be preferred or required. General anesthesia can be more rapidly administered in the case of an emergency (e.g., severe fetal distress). If the mother has a coagulation disorder that would be complicated by a drop in blood pressure (a risk with regional anesthesia), general anesthesia is an alternative. General anesthesia is also used for some of the more complicated and prolonged obstetric and gynecologic surgeries.

Obstetric sonogram *see* **Pelvic ultrasound**

Obstetrical emergencies

Definition

Obstetrical emergencies are life-threatening medical conditions that occur in **pregnancy** or during or after labor and delivery.

Description

There are a number of illnesses and disorders of pregnancy that can threaten the well-being of both mother and child. Obstetrical emergencies may also occur during active labor, and after delivery (postpartum).

Obstetrical emergencies of pregnancy

ECTOPIC PREGNANCY. An ectopic, or tubal, pregnancy occurs when the fertilized egg implants itself in the fallopian tube rather than the uterine wall. If the

pregnancy is not terminated at an early stage, the fallopian tube will rupture, causing internal hemorrhaging and potentially resulting in permanent **infertility**.

PLACENTAL ABRUPTION. Also called *abruptio placenta*, **placental abruption** occurs when the placenta separates from the uterus prematurely, causing bleeding and contractions. If more than 50% of the placenta separates, both the fetus and mother are at risk.

PLACENTA PREVIA. When the placenta attaches to the mouth of the uterus and partially or completely blocks the cervix, the position is termed *placenta previa* (or low-lying placenta). **Placenta previa** can result in premature bleeding and possible postpartum hemorrhage.

PREECLAMPSIA/ECLAMPSIA. Preeclampsia (toxemia), or pregnancy-induced high blood pressure, causes severe **edema** (swelling due to water retention) and can impair kidney and liver function. The condition occurs in approximately 5% of all United States pregnancies. If it progresses to **eclampsia**, toxemia is potentially fatal for mother and child.

PREMATURE RUPTURE OF MEMBRANES (PROM). Premature rupture of membranes is the breaking of the bag of waters (amniotic fluid) before contractions or labor begins. The situation is only considered an emergency if the break occurs before 37 weeks and results in significant leakage of amniotic fluid and/or infection of the amniotic sac.

Obstetrical emergencies during labor and delivery

AMNIOTIC FLUID EMBOLISM. A rare but frequently fatal complication of labor, this condition occurs when amniotic fluid embolizes from the amniotic sac and through the veins of the uterus and into the circulatory system of the mother. The fetal cells present in the fluid then block or clog the pulmonary artery, resulting in **heart attack**. This complication can also happen during pregnancy, but usually occurs in the presence of strong contractions.

INVERSION OR RUPTURE OF UTERUS. During labor, a weak spot in the uterus (such as a scar or a uterine wall that is thinned by a **multiple pregnancy**) may tear, resulting in a uterine rupture. In certain circumstances, a portion of the placenta may stay attached to the wall and will pull the uterus out with it during delivery. This is called uterine inversion.

PLACENTA ACCRETA. *Placenta accreta* occurs when the placenta is implanted too deeply into the uterine wall, and will not detach during the late stages of **childbirth**, resulting in uncontrolled bleeding.

PROLAPSED UMBILICAL CORD. A prolapse of the umbilical cord occurs when the cord is pushed down into the cervix or vagina. If the cord becomes compressed, the oxygen supply to the fetus could be diminished, resulting in brain damage or possible death.

SHOULDER DYSTOCIA. Shoulder dystocia occurs when the baby's shoulder(s) becomes wedged in the birth canal after the head has been delivered.

Obstetrical emergencies postpartum

POSTPARTUM HEMORRHAGE OR INFECTION. Severe bleeding or uterine infection occurring after delivery is a serious, potentially fatal situation.

Causes and symptoms

Obstetrical emergencies can be caused by a number of factors, including **stress**, **trauma**, genetics, and other variables. In some cases, past medical history, including previous pregnancies and deliveries, may help an obstetrician anticipate the possibility of complications.

Signs and symptoms of an obstetrical emergency include, but are not limited to:

- Diminished fetal activity. In the late third trimester, fewer than 10 movements in a two-hour period may indicate that the fetus is in distress.
- Abnormal bleeding. During pregnancy, brown or white to pink vaginal discharge is normal, bright red blood or blood containing large clots is not. After delivery, continual blood loss of more than 500 mL indicates hemorrhage.
- Leaking amniotic fluid. Amniotic fluid is straw-colored and may easily be confused with urine leakage, but can be differentiated by its slightly sweet odor.
- Severe abdominal pain. Stomach or lower back pain can indicate preeclampsia or an undiagnosed ectopic pregnancy. Postpartum stomach pain can be a sign of infection or hemorrhage.
- Contractions. Regular contractions before 37 weeks of gestation can signal the onset of preterm labor due to obstetrical complications.
- Abrupt and rapid increase in blood pressure. Hypertension is one of the first signs of toxemia.
- Edema. Sudden and significant swelling of hands and feet caused by fluid retention from toxemia.
- Unpleasant smelling vaginal discharge. A thick, malodorous discharge from the vagina can indicate a postpartum infection.
- Fever. Fever may indicate an active infection.

WWW.BOOKBAZ.IR

- Loss of consciousness. Shock due to blood loss (hemorrhage) or amniotic embolism can precipitate a loss of consciousness in the mother.
- Blurred vision and headaches. Vision problems and headache are possible symptoms of preeclampsia.

Diagnosis

Diagnosis of an obstetrical emergency typically takes place in a hospital or other urgent care facility. A specialist will take the patient's medical history and perform a pelvic and general **physical examination**. The mother's vital signs are taken, and if preeclampsia is suspected, blood pressure may be monitored over a period of time. The fetal heartbeat is assessed with a doppler stethoscope, and diagnostic blood and urine tests of the mother may also be performed, including laboratory analysis for protein and/or bacterial infection. An **abdominal ultrasound** may aid in the diagnosis of any condition that involves a malpositioned placenta, such as placenta previa or placenta abruption.

In cases where an obstetrical complication is suspected, a fetal heart monitor is positioned externally on the mother's abdomen. If the fetal heart rate is erratic or weak, or if it does not respond to movement, the fetus may be in distress. A biophysical profile (BPP) may also be performed to evaluate the health of the fetus. The BPP uses data from an **ultrasound** examination to analyze the fetus size, movement, heart rate, and surrounding amniotic fluid.

If the mother's membranes have ruptured and her cervix is partially dilated, an internal fetal scalp electrode can be inserted through the vagina to assess heart rate. A fetal oximetry monitor that measures the oxygen saturation levels of the fetus may also be attached to the scalp.

Treatment

Obstetrical emergencies of pregnancy

ECTOPIC PREGNANCY. Treatment of an **ectopic pregnancy** is laparoscopic surgical removal of the fertilized ovum. If the fallopian tube has burst or been damaged, further surgery will be necessary.

PLACENTAL ABRUPTION. In mild cases of placental abruption, bed rest may prevent further separation of the placenta and stem bleeding. If a significant abruption (more than 50%) occurs, the fetus may have to be delivered immediately and a blood **transfusion** may be required.

PLACENTA PREVIA. Hospitalization or highly restricted at-home bed rest is usually recommended if placenta previa is diagnosed after the twentieth week of pregnancy. If the fetus is at least 36 weeks old and the lungs are mature, a **cesarean section** is performed to deliver the baby.

PREECLAMPSIA/ECLAMPSIA. Treatment of preeclampsia depends upon the age of the fetus and the acuteness of the condition. A woman near full term who has only mild toxemia may have labor induced to deliver the child as soon as possible. Severe preeclampsia in a woman near term also calls for immediate delivery of the child, as this is the only known cure for the condition. However, if the fetus is under 28 weeks, the mother may be hospitalized and **steroids** may be administered to try to hasten lung development in the fetus. If the life of the mother or fetus appears to be in danger, the baby is delivered immediately, usually by cesarean section.

PREMATURE RUPTURE OF MEMBRANES (PROM). If PROM occurs before 37 weeks and/or results in significant leakage of amniotic fluid, a course of intravenous **antibiotics** is started. A culture of the cervix may be taken to analyze for the presence of bacterial infection. If the fetus is close to term, labor is typically induced if contractions do not start within 24 hours of rupture.

Obstetrical emergencies during labor and delivery

AMNIOTIC FLUID EMBOLISM. The stress of contractions can cause this complication, which has a high mortality rate. Administering steroids to the mother and delivering the fetus as soon as possible is the standard treatment.

INVERSION OR RUPTURE OF UTERUS. An inverted uterus is either manually or surgical replaced to the proper position. A ruptured uterus is repaired if possible, although if the damage is extreme, a **hysterectomy** (removal of the uterus) may be performed. A blood transfusion may be required in either case if hemorrhaging occurs.

PLACENTA ACCRETA. Women who experience placenta accreta will typically need to have their placenta surgically removed after delivery. Hysterectomy is necessary in some cases.

PROLAPSED UMBILICAL CORD. Saline may be infused into the vagina to relieve the compression. If the cord has prolapsed out the vaginal opening, it may be replaced, but immediate delivery by cesarean section is usually indicated.

Obstetrical emergencies postpartum

POSTPARTUM HEMORRHAGE OR INFECTION. The source of the hemorrhage is determined, and blood

KEY TERMS

Amniotic fluid—The liquid in the placental sac that cushions the fetus and regulates temperature in the placental environment. Amniotic fluid also contains fetal cells.

Cesarean section—The surgical delivery of a fetus through an incision in the uterus.

Embolism—Blood vessel obstruction by a blood clot or other substance (e.g., air, cell matter).

Episiotomy—Incision of the perineum, the area between the vulva and the anus, to assist delivery and avoid severe tearing of the perineum.

Laparoscopic—A minimally-invasive surgical or diagnostic procedure that uses a flexible endoscope (laparoscope) to view and operate on structures in the abdomen.

Postpartum—After childbirth.

transfusion and IV fluids are given as necessary. Oxytocic drugs may be administered to encourage contraction of the uterus. Retained placenta is a frequent cause of persistent bleeding, and surgical removal of the remaining fragments (curettage) may be required. Surgical repair of lacerations to the birth canal or uterus may be required. Drugs that encourage coagulation (clotting) of the blood may be administered to stem the bleeding. Infrequently, hysterectomy is required.

In cases of infection, a course of intravenous antibiotics is prescribed. Most postpartum infections occur in the endometrium, or lining of the uterus, and may be also caused by a piece of retained placenta. If this is the case, it will also require surgical removal.

SHOULDER DYSTOCIA. The mother is usually positioned with her knees to her chest, known as the McRoberts maneuver, in an effort to free the child's shoulder. An **episiotomy** is also performed to widen the vaginal opening. If the shoulder cannot be dislodged from the pelvis, the baby's clavicle (collarbone) may have to be broken to complete the delivery before a lack of oxygen causes brain damage to the infant.

Prognosis

If a fetus is close to full-term (37 weeks) and the complication is detected early enough, the prognosis is usually good for mother and child. With advances in **neonatal care**, approximately 85% of infants weighing less than 3 lbs 5 oz survive, and these infants are being delivered at 28 weeks and younger. However, preterm infants have a greater chance of serious medical problems, and developmental disabilities occur in 25–50%. They also have a higher incidence of **learning disorders**, and are four to six times more likely to be diagnosed with attention-deficit hyperactivity disorder (**ADHD**).

Prevention

Proper prenatal care is the best prevention for obstetrical emergencies. When complications of pregnancy do arise, pregnant women who see their OB/GYN on a regular basis are more likely to get an early diagnosis, and with it, the best chance for fast and effective treatment. In addition, eating right and taking prenatal **vitamins** and supplements as recommended by a physician will also contribute to the health of both mother and child.

Paula Anne Ford-Martin

Occupational therapy

Definition

Occupational therapy (OT) is a holistic, patient-centered, occupation-based approach to life-skills development for people with developmental disabilities, physical or mental diseases, injuries, or other health problems. Occupational therapy addresses physical, psychological, social, and environmental factors that interfere with functioning in various ways.

Purpose

The goal of occupational therapy is to help patients develop the skills and obtain the support necessary to live productive lives as independently as possible, to improve quality of life, and to decrease hospitalization and institutionalization.

Occupational therapy is used to treat a variety of physical and developmental disabilities, including:

- cerebral palsy, spina bifida, and other birth injuries and defects

WWW.BOOKBAZ.IR

- Down syndrome
- muscular dystrophy, arthritis, multiple sclerosis, or other serious chronic conditions
- developmental delays
- intellectual disabilities (ID)
- autism
- learning disabilities
- attention deficit disorder (ADD)
- sensory processing/integrative disorders
- broken bones and other injuries from falls, sports injuries, or accidents
- brain and spinal cord injuries
- hand injuries
- amputations
- post-surgical conditions
- burns
- work-related injuries including lower-back problems and repetitive stress injury (RSI)
- limitations following a heart attack or stroke
- diabetes
- cancer
- Parkinson's disease

In recent years occupational therapy has expanded its scope into new areas, including:

- mental health and behavioral problems such as depression, dementia, Alzheimer's disease, schizophrenia, posttraumatic stress, substance abuse, and eating disorders
- visual impairment
- home modification
- ergonomics consulting

Demographics

The demand for occupational therapy is expected to continue grow, as the baby-boomer generation (those born between 1945 and 1965) ages and requires various services, such as modifications in order to stay in their homes. As people live longer despite serious illness and disability, occupational therapy will facilitate independence in daily living and working. For example, **stroke** is the major cause of disability in adults and it is estimated that 5.4 million Americans are living with the effects of stroke.

Description

Occupational therapy provides direct care to patients with physical, developmental, and mental disabilities, in settings that include:

- long-term-care (LTC) facilities
- skilled-nursing facilities (SNFs) and nursing homes
- assisted-living facilities
- mental-health facilities
- hospitals
- rehabilitation centers
- outpatient and children's clinics
- adult daycare centers
- home healthcare agencies
- schools
- foster-care residences
- group and private homes
- sheltered workplaces
- senior centers
- wellness education programs
- business-to-business consulting firms that specialize in ergonomics
- private practices

Occupational therapists may work with and receive referrals from:

- physicians and nurses
- psychologists and psychiatrists
- other health professionals
- social workers
- case managers
- courts
- teachers, and vocational and guidance counselors
- foster-care providers
- families
- clients themselves

Regardless of the setting, occupational therapy is centered on the needs of patients and the environments in which they live. The therapist may perform activities-of-daily-living (ADL) evaluations to determine patients' competence and independence in performing daily tasks at home, work or school, and within their social environments. Examples of activities of daily living might include dialing a phone, paying bills, using a computer, or driving a car. Children are evaluated by their abilities to perform activities such as writing the alphabet, drawing shapes, playing games, tying shoes, brushing teeth, combing hair, or squeezing a special grip meter. Following the evaluation the occupational therapist may implement a treatment plan or interventions to facilitate a more independent lifestyle. The OT may evaluate the need for special equipment such as splints, wheelchairs, bathing equipment, dressing devices, or communication aids.

Occupational therapists work within six broad fields:

- rehabilitation, disability, and participation
- productive aging
- children and youth
- mental health
- health and wellness
- work and industry

Within these broad categories occupational therapy can involve a wide range of interventions, including:

- exercises for improving mobility
- prevention of falls
- sensory integration
- home modifications for independent living
- analysis of home lighting and contrast for the visually impaired
- slings or splints to provide support to body parts
- assistive devices for activities such as opening a jar, putting on shoes, or taking a bath or shower
- chronic disease management
- home healthcare
- driving and alternative transportation
- stress management
- communication skills
- assertiveness skills
- problem solving
- time management
- management of medications
- safety in the home and community
- pursuing vocational interests
- developing self-awareness
- interpersonal and social skills
- hygiene
- parenting skills

Occupational therapy provides early intervention for children with physical, sensory, or cognitive disabilities in daycare centers, preschools, and elementary and high schools. Occupational therapists also have an important role in disaster relief. OT can help children with disabilities become as independent as possible or successfully return to school after a long illness or serious injury. Childhood interventions may involve:

- working with children to brush their teeth, dress, tie their shoes, and feed themselves
- handwriting and drawing to improve finger dexterity
- coloring within the lines
- working on hand-eye coordination by hitting a target, batting a ball, or copying from the blackboard
- using a computer
- alternative ways for playing popular games
- teaching strategies for improving focus and attentiveness
- homework help
- managing a wheelchair in school
- interacting with others and improving social skills
- learning anger-management skills, such as writing about feelings or pursuing a physical activity

Occupational therapy often breaks tasks down into smaller steps, such as learning a song note by note. To learn to bathe, the client may first learn to turn on the water, then adjust the temperature, find soap and a towel, and then climb in the tub.

Occupational therapy also includes:

- adapting the home, school, or work environment to a client's needs
- developing educational programs, experiential learning, and treatment groups or classes
- housing and job placement, and ongoing monitoring
- assisting with client-run support groups
- consulting with employers about the requirements of the Americans with Disabilities Act
- developing transitional work programs

Occupational therapy in the workplace may involve:

- evaluating a worker on the job
- recommending job modifications
- implementing and supervising a return-to-work program
- monitoring progress
- improving productivity
- ergonomics to maximize function and comfort and minimize repetitive stress injuries from jobs such as typing or assembly-line work

Origins

Occupational therapy developed as a healthcare specialty during World War I, to work with soldiers suffering from shell **shock**, amputations, and other injuries. In the early twentieth century, occupational therapists also treated **tuberculosis** and **polio** patients. The advent of managed healthcare in the United States dramatically expanded the role of occupational therapy.

WWW.BOOKBAZ.IR

KEY TERMS

Activities of daily living (ADL)—The skills and practices that determine how well individuals function in their daily lives and relate to and participate in their environment.

Alzheimer's disease—A progressive, neurodegenerative disease characterized by loss of function and death of nerve cells in several areas of the brain, leading to loss of mental functions, such as memory and learning. Alzheimer's disease is the most common cause of dementia.

Arthritis—Inflammation of one or more joints.

Attention deficit disorder (ADD)—A condition characterized by age-inappropriate attention span; often accompanied by age-inappropriate hyperactivity and impulsive behavior.

Autism—A variable developmental disorder that includes an impaired ability to communicate and form normal social relationships.

Ergonomics—The study of the relationship between people and their working environment.

Home modification—The altering of the physical environment of the home to remove hazards and provide a more functional environment; examples include the installation of grab bars and no-slip foot mats in the bathroom to prevent falls.

Parkinson's disease—A disorder of the brain characterized by shaking and difficulty with walking, movement, and coordination. The disease is associated with damage to a part of the brain that controls muscle movement.

Repetitive stress injury; repetitive strain injury (RSI)—Any of various musculoskeletal disorders—such as tendonitis or carpal tunnel syndrome—that are caused by cumulative damage to muscles, tendons, ligaments, nerves, or joints from highly repetitive movements, such as of the hand, wrist, arm, or shoulder.

Stroke—A sudden diminishing or loss of consciousness, sensation, or voluntary movement from a rupture or obstruction of a blood vessel in the brain.

Results

In addition to helping the injured and disabled to perform everyday tasks, live independently, and work or attend school, occupational therapy can improve skills and help prevent injuries in people of any age and ability. Benefits of occupational therapy include:

- assessments of performance and skills
- customized treatment programs for improving clients' abilities to perform daily activities
- home and workplace evaluations and recommendations for adaptations
- guidance for family members and caregivers
- providing fun, positive activities for improving children's cognitive, physical, and motor skills and enhancing self-esteem and sense of accomplishment

Preparation

Client attitude and cooperation are key to successful occupational therapy. Clients should be active participants, aware of the short-term and long-term goals of their therapy and able to communicate with their therapists.

Aftercare

Clients must continue to practice what they have learned in their occupational therapy and make appropriate adjustments in their lives. Many clients have long-term monitoring and assessments.

Training and certification

Occupational therapists have master's or doctoral degrees in OT. Practitioners must complete supervised clinical internships in a variety of healthcare settings and pass a national examination. Occupational therapy assistants (OTAs) usually have associate degrees. OTAs are able to carry out treatment plans developed by occupational therapists, but do not perform evaluations and assessments. The National Board for Certification in Occupational Therapy provides certification for the profession.

Regular continuing education courses and additional training are necessary for occupational therapists to maintain competency. Practitioners can take advantage of continuing education courses offered by the American Occupational Therapy Association, as well as online courses, annual conference and exposition workshops, and educational sessions offered by leaders in occupational therapy.

The practice of occupational therapy is regulated in every state and licensing of occupational therapists is required in most states. Licensure defines the scope of OT practice and provides guidance to facilities and healthcare providers on the appropriate applications of occupational therapy.

Oil spills: health effects

Definition

Along with fouling marine and coastal ecosystems, offshore oil spills also pose potential health hazards for humans, both as workers respond to the spill and as oil impacts the environment where people live. After the 1989 *Exxon Valdez* oil spill that occurred in Prince William Sound off the coast of Alaska, one study published in the *American Journal of Psychiatry* showed that residents living in areas impacted by the spill were more likely to suffer mental health problems than the general population, even years after the spill. Few studies were conducted, however, on the health impacts of workers who were exposed to the oil during clean-up efforts. In the wake of the 2010 BP *Deepwater Horizon* oil spill in the Gulf of Mexico, the information remains inconclusive on the actual health hazards that could result from the spill. At a gathering of **public health** experts in late June 2010, U.S. Surgeon General Regina Benjamin described some scientists as predicting little or no toxic effect from short-term exposure to the oil, while indicating that "other scientists express serious concerns about the potential short-term and long-term impacts the exposure to oil and dispersants could have on the health of responders and our communities."

Demographics

Virtually everyone who lives near a coastline could be affected by an oil spill, as more than 38,000 oil tankers traverse the world's oceans and seas, delivering oil in its various stages from ports near the extraction site to ports where it is refined and later consumed. Offshore drilling fields are located primarily in the North Sea, the Gulf of Mexico, the South China Sea, and off the coasts of Nigeria, Angola, Brazil, the Canadian Provinces of Nova Scotia and Newfoundland, and eastern Russia. Large land-based oil fields are located in the Middle East, the United States, Russia, Mexico, and Venezuela. Persons especially at risk to the potentially harmful effects of oil exposure include those with existing respiratory problems, pregnant women, and children.

Description

Although the composition of crude oil varies somewhat according to its source, crude oil is a naturally occurring brown or black liquid that is composed of a mixture of hydrocarbons and other organic compounds. Crude oil is toxic, flammable, and contains volatile organic compounds (VOCs) that have known adverse effects on human health. OVCs include benzene, a carcinogen, and polycyclic aromatic hydrocarbons (PACs), which are toxic to the central nervous system. The VOCs evaporate easily, moving from the oil into the air, and can be carried by prevailing winds miles from the source of the spill and into coastal communities. There is evidence that some dispersants, solvents, and collecting agents used to manage the spill, when combined with the oil, can potentiate

WWW.BOOKBAZ.IR

KEY TERMS

Carcinogen—An agent that is known to cause cancer.

Dispersant—Chemicals that break up spilled oil into small particles that can be further scattered and broken down by water and wind, thus sparing oil damage to marine and coastal environments.

Mousse oil—Crude oil that has emulsified or weathered, mixed with dispersants, water, and marine material to form a spongy, light brown, mousse-like material.

Post-traumatic stress syndrome—A type of severe anxiety disorder that can develop after experiencing traumatic events or situations.

Teratogen—An agent that is known to disturb the development of an embryo or fetus.

Volatile organic compounds—VOCs, a large class of carbon-based chemicals that release gases into the air as they evaporate at room temperature. Found both in natural sources such as living trees, decomposing vegetation, and crude oil, and in manmade sources such as solvents, adhesives, and gasoline, VOCs help form ozone at ground levels and are major air contaminants.

some of the toxic effects of crude oil alone. Harmful airborne pollution released by burning the oil on the surface of a spill is also a health concern for both responders and local populations on nearby shores.

Causes and symptoms

People are exposed to oil-spill toxins through direct contact with oil on the skin, by breathing VOCs and other chemicals released into the air, or through oil-contaminated sand, soil, water, or food. Multiple exposure paths can occur simultaneously. All adverse reactions to oil are dependent upon both the duration of the exposure and a person's particular susceptibility to the particular toxins in the oil.

Hundreds of workers cleaning Alaskan shores, marshes, and oiled waterways during the *Exxon Valdez* spill complained of skin **rashes**, **dizziness**, headaches, and nausea during their work and for a short time afterwards. Some experienced longer-lasting symptoms including **shortness of breath**, muscle aches, and neurological problems including **numbness and tingling** of the extremities.

Public health officials along the Gulf coast are monitoring for these symptoms in communities affected by the *Deepwater Horizon* spill, as well as establishing data-collection methods to document possible longer-term consequences of oil exposure, such as kidney damage, **birth defects**, and cancer. As of late 2014, complaints among coastal residents, along with workers cleaning the oil both on land and at sea, have included skin rashes, headaches, nausea, and irritation in the throat and eyes. Several workers have also experienced heat **stress** due to working outside in hot and humid conditions.

Although high levels of mental and emotional stress are expected during a natural or technological disaster, the *Deepwater Horizon* oil spill impacted an area whose vulnerable population was still recovering from hurricanes Ivan, Katrina, and Rita. Benjamin Springgate, a physician and public health researcher at Tulane University in New Orleans, estimated that more than 30% of people in the impact zone of Hurricane Katrina experienced symptoms of **anxiety**, depression, or other mental illness after the storm, and also predicted that the impacts of the *Deepwater Horizon* oil spill on the mental health of coastal residents will be a long-term situation. The most frequent symptoms of stress-related mental disorders include feelings of hopelessness, disturbances in sleep patterns, lack of concentration, mood swings, irritability, inability to make productive decisions, nightmares or persistent memories of disturbing or frightening events, and general anxiety.

Diagnosis

The most frequent mental disorders diagnosed among people affected by an oil spill include post-traumatic syndrome, **anxiety disorders**, and depression. These are diagnosed by a psychiatrist or other mental health professional, mostly after a careful discussion of the symptoms. Other oil-spill-related illnesses are diagnosed according to the nature of symptoms, **physical examination**, and additional diagnostic or laboratory tests. Chemical **pneumonia**, for example, is caused by respiratory irritation from exposure to VOCs or other chemicals, followed by inflammation and decreased lung function. It is most often diagnosed by history and physical examination, especially auscultation of (listening to) the lungs, examination of the sputum, and x ray, as are other types of pneumonia.

Treatment

Mousse oil on the skin or tar balls can be cleaned with soap and water or mineral oil. Treatment of more serious illnesses of various body systems and organs

exposed to oil depends on the system affected, the nature and length of the exposure, and the symptoms present. The U.S. Department of Health and Human Services has created a $10 million fund to track *Deepwater Horizon*-related illnesses in order to get a clear picture of their nature and to devise the most effective treatments. Also, more than 14,000 oil spill workers have volunteered to participate in a similar study for the Centers for Disease Control and Prevention (CDC).

Prognosis

The full effects of the *Deepwater Horizon* oil spill on the health and well-being of people living in communities along the northern Gulf of Mexico will not be fully known until the oil is cleaned and the physical, ecological, and economic environments are restored, a process that will take years. Scientists anticipate that the information gained from careful study of the detrimental effects of the oil spill on the physical and mental health of spill responders and Gulf coast residents will help identify both short-term and long-term health issues related to the spill, and allow for an effective response now and during future technological disasters.

Prevention

Avoiding contact with the oil is the most effective way to prevent negative health effects from an oil spill. Beaches along the northern Gulf Coast have "no swimming" signs and flags posted in locations where oil from the *Deepwater Horizon* spill has impacted the shore. Workers both offshore and at the spill site utilize a variety of personal protective equipment including gloves, white plastic protective (hazmat) suits, respirators, and other barrier methods designed to prevent exposure to oil.

Authorities have closed more than 30% of Gulf Coast federal fishing waters to both commercial and personal fishing in order to prevent oil-contaminated fish and shellfish from entering the food supply. Increased inspection of allowable catches helps ensure that Gulf fish making its way to the market are uncontaminated and of the usual high quality.

When winds bring fumes from the spill onshore, residents with existing respiratory problems are advised to remain indoors with re-circulating air. Pregnant women should avoid oil-contaminated beaches or air, as components of crude oil are known teratogens and exposure to crude oil can result in decreased fetal survival. Children are also particularly vulnerable to DNA damage from long-term exposure to airborne toxins emanating from oil spills. The U.S. Environmental Protection Agency has set up more than 100 monitoring stations along affected areas of the Gulf Coast to detect unhealthy levels of VOCs, overall ozone, and particulate matter in the air, and to issue regular air quality reports.

Innovative approaches are being taken along the Gulf Coast to reach people who may be experiencing symptoms of stress, but are unlikely to seek help for them. Peer listeners have been trained to identify signs of distress during conversation, to offer encouragement that help is available, and to provide referrals to nearby mental health services. Personnel with knowledge of and sensitivities to local cultures, including those who speak Vietnamese and Spanish, are also available to hear the needs and concerns of fishermen and other close-knit communities.

Oligomenorrhea

Definition

Medical dictionaries define oligomenorrhea as infrequent or very light menstruation. But physicians typically apply a narrower definition, restricting the diagnosis of oligomenorrhea to women whose periods were regularly established before they developed problems with infrequent flow. With oligomenorrhea, menstrual periods occur at intervals of greater than 35 days, with only four to nine periods in a year.

Description

True oligomenorrhea cannot occur until menstrual periods have been established. In the United States, 97.5% of women have begun normal menstrual cycles by age 16. The complete absence of menstruation, whether menstrual periods never start or whether they stop after having been established, is called **amenorrhea**. Oligomenorrhea can become amenorrhea if menstruation stops for six months or more.

It is quite common for women at the beginning and end of their reproductive lives to miss or have irregular periods. This is normal and is usually the result of imperfect coordination between the hypothalamus, the pituitary gland, and the ovaries. For no apparent reason, a few women menstruate (with ovulation occurring) on a regular schedule as infrequently as once every two months. For them that schedule is normal and not a cause for concern.

Women with **polycystic ovary syndrome** (PCOS) are also likely to suffer from oligomenorrhea. PCOS is a condition in which the ovaries become filled with small cysts. Women with PCOS show menstrual irregularities that range from oligomenorrhea and amenorrhea on the one hand to very heavy, irregular periods on the other. The condition affects about 6% of premenopausal women and is related to excess androgen production.

Other physical and emotional factors also cause a woman to miss periods. These include:

- emotional stress
- chronic illness
- poor nutrition
- eating disorders such as anorexia nervosa
- excessive exercise
- estrogen-secreting tumors
- illicit use of anabolic steriod drugs to enhance athletic performance

Professional ballet dancers, gymnasts, and ice skaters are especially at risk for oligomenorrhea because they combine strenuous physical activity with a diet intended to keep their weight down. Menstrual irregularities are now known to be one of the three disorders comprising the so-called "female athlete triad," the other disorders being disordered eating and **osteoporosis**. The triad was first formally named at the annual meeting of the American College of Sports Medicine in 1993, but doctors were aware of the combination of bone mineral loss, **stress fractures**, **eating disorders**, and participation in women's sports for several decades before the triad was named. Women's coaches have become increasingly aware of the problem since the early 1990s, and are encouraging female athletes to seek medical advice.

Causes and symptoms

Symptoms of oligomenorrhea include:

- menstrual periods at intervals of more than 35 days
- irregular menstrual periods with unpredictable flow
- some women with oligomenorrhea may have difficulty conceiving

Oligomenorrhea that occurs in adolescents is often caused by immaturity or lack of synchronization between the hypothalamus, pituitary gland, and ovaries. The hypothalamus is part of the brain that controls body temperature, cellular metabolism, and basic functions such as eating, sleeping, and reproduction. It secretes hormones that regulate the pituitary gland.

The pituitary gland is then stimulated to produce hormones that affect growth and reproduction. At the beginning and end of a woman's reproductive life, some of these hormone messages may not be synchronized, causing menstrual irregularities.

In PCOS, oligomenorrhea is probably caused by inappropriate levels of both female and male hormones. Male hormones are produced in small quantities by all women, but in women with PCOS, levels of male hormone (androgens) are slightly higher than in other women. More recently, however, some researchers are hypothesizing that the ovaries of women with PCOS are abnormal in other respects. In 2003, a group of researchers in London reported that there are fundamental differences between the development of egg follicles in normal ovaries and follicle development in the ovaries of women with PCOS.

In athletes, models, actresses, dancers, and women with **anorexia nervosa**, oligomenorrhea occurs because the ratio of body fat to weight drops too low.

Diagnosis

History and physical examination

Diagnosis of oligomenorrhea begins with the patient informing the doctor about infrequent periods. The doctor will ask for a detailed description of the problem and take a history of how long it has existed and any patterns the patient has observed. A woman can assist the doctor in diagnosing the cause of oligomenorrhea by keeping a record of the time, frequency, length, and quantity of bleeding. She should also tell the doctor about any recent illnesses, including long-standing conditions like **diabetes mellitus**. The doctor may also inquire about the patient's diet, **exercise** patterns, sexual activity, contraceptive use, current medications, or past surgical procedures.

The doctor will then perform a **physical examination** to evaluate the patient's weight in proportion to her height, to check for signs of normal sexual development, to make sure the heart rhythm and other vital signs are normal, and to palpate (feel) the thyroid gland for evidence of swelling.

In the case of female athletes, the doctor may need to establish a relationship of trust with the patient before asking about such matters as diet, practice and workout schedules, and the use of such drugs as **steroids** or ephedrine. The presence of stress fractures in young women should be investigated. In some cases, the doctor may give the patients the Eating Disorder Inventory (EDI) or a similar screening questionnaire to help determine whether the patient is at risk for developing anorexia or bulimia.

Laboratory tests

After taking the woman's history, the gynecologist or family practitioner does a pelvic examination and **Pap test**. To rule out specific causes of oligomenorrhea, the doctor may also do a **pregnancy** test and blood tests to check the level of thyroid hormone. Based on the initial test results, the doctor may want to do tests to determine the level of other hormones that play a role in reproduction.

More sensitive monoclonal assays have been developed for measuring hormone levels in the blood serum of women with PCOS, thus allowing earlier and more accurate diagnosis.

Imaging studies

In some cases the doctor may order an **ultrasound** study of the pelvic region to check for anatomical abnormalities, or x rays or a **bone scan** to check for bone fractures. In a few cases the doctor may order an MRI to rule out tumors affecting the hypothalamus or pituitary gland.

Treatment

Treatment of oligomenorrhea depends on the cause. In adolescents and women near **menopause**, oligomenorrhea usually needs no treatment. For some athletes, changes in training routines and eating habits may be enough to return the woman to a regular menstrual cycle.

Most patients suffering from oligomenorrhea are treated with birth-control pills. Other women, including those with PCOS, are treated with hormones. Prescribed hormones depend on which particular hormones are deficient or out of balance. When oligomenorrhea is associated with an eating disorder or the female athlete triad, the underlying condition must be treated. Consultation with a psychiatrist and nutritionist is usually necessary to manage an eating disorder. Female athletes may require **physical therapy** or **rehabilitation** as well.

Alternatives

As with conventional medicial treatments, alternative treatments are based on the cause of the condition. If a hormonal imbalance is revealed by laboratory testing, hormone replacements that are more "natural" for the body (including tri-estrogen and natural progesterone) are recommended. Glandular therapy can assist in bringing about a balance in the glands involved in the reproductive cycle, including the hypothalmus, pituitary, thyroid, ovarian, and adrenal glands. Since homeopathy and **acupuncture** work on deep, energetic levels to rebalance the body, these two modalities may be helpful in treating oligomenorrhea. Western and Chinese herbal medicines also can be very effective. Herbs used to treat oligomenorrhea include dong quai (*Angelica sinensis*), black cohosh (*Cimicifuga racemosa*), and chaste tree (*Vitex agnus-castus*). Herbal preparations used to bring on the menstrual period are known as emmenagogues. For some women, **meditation**, **guided imagery**, and visualization can play a key role in the treatment of oligomenorrhea by relieving emotional stress.

Diet and adequate **nutrition**, including adequate protein, essential fatty acids, whole grains, and fresh fruits and vegetables, are important for every woman,

WWW.BOOKBAZ.IR

KEY TERMS

Anorexia nervosa—A disorder of the mind and body in which people starve themselves in a desire to be thin, despite being of normal or below normal body weight for their size and age.

Cyst—An abnormal sac containing fluid or semi-solid material.

Emmenagogue—A medication or herbal preparation given to bring on a woman's menstrual period.

Female athlete triad—A combination of disorders frequently found in female athletes that includes disordered eating, osteoporosis, and oligo- or amenorrhea. The triad was first officially named in 1993.

Osteoporosis—The excessive loss of calcium from the bones, causing the bones to become fragile and break easily. Women who are not menstruating are especially vulnerable to this condition because estrogen, a hormone that protects bones against calcium loss, decreases drastically after menopause.

especially if deficiencies are present or if she regularly exercises very strenuously. Female athletes at the high school or college level should consult a nutritionist to make sure that they are eating a well-balanced diet that is adequate to maintain a healthy weight for their height. Girls participating in dance or in sports that emphasize weight control or a slender body type (gymnastics, track and field, swimming, and cheerleading) are at higher risk of developing eating disorders than those that are involved in such sports as softball, weight lifting, or basketball. In some cases the athlete may be given **calcium** or **vitamin D** supplements to lower the risk of osteoporosis.

Many women, including those with PCOS, are successfully treated with hormones for oligomenorrhea. They have more frequent periods and begin ovulating during their menstrual cycle, restoring their fertility.

For women who do not respond to hormones or who continue to have an underlying condition that causes oligomenorrhea, the outlook is less positive. Women who have oligomenorrhea may have difficulty conceiving children and may receive fertility drugs. The absence of adequate estrogen increases risk for bone loss (osteoporosis) and cardiovascular disease. Women who do not have regular periods also are more likely to develop uterine cancer. Oligomenorrhea can become amenorrhea at any time, increasing the chance of having these complications.

Prevention

Oligomenorrhea is preventable only in women whose low body fat to weight ratio is keeping them from maintaining a regular menstrual cycle. Adequate nutrition and a less vigorous training schedules will normally prevent oligomenorrhea. When oligomenorrhea is caused by hormonal factors, it is not preventable, but it is often treatable.

Omega-3 and omega-6 fatty acids

Definition

Omega-3 (n-3) and omega-6 (n-6) fatty acids are long-chain fatty polyunsaturated **fats** (PUFAs) that are vital to human health. These fats are crucial structural components of cell membranes that enable the body to function. Dietary sources of omega-3 fats include fatty fish such as tuna and salmon and plant-based foods such as **flaxseed** and walnuts. Omega-6 fats are found in found in plant-based oils, such as corn oil and in plant-based foods such as pecans and Brazil nuts.

Purpose

Omega-3 and omega-6 fatty acids are important to many life processes. They are vital structural components of cell membranes that enable the body to function and are crucial to brain function. The three main omega-3 fatty-acids are eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and alpha-linolenic acid (ALA). DHA and EPA are especially important in the brain, retina, and in organs including the kidneys and liver. DHA is the primary n-3 in the brain, where it is located in the fatty membranes that surround nerve cells.

Omega fatty acids help to stimulate skin and hair growth, maintain bone health, and regulate **metabolism**, according to the University of Maryland Medical Center (UMMC). In the body, n-3 and n-6 synthesize prostaglandins, hormone-like substances that assist in controlling functions such as blood pressure, blood clotting, the gastrointestinal tract, and the inflammatory process. Omega-3 fatty acids are involved in muscle relaxation and contraction, blood clotting, growth, digestion, fertility, cell division, and the movement of **calcium** and other substances in and out of cells, according to the National Center for Complementary and Alternative Medicine (NCCAM).

According to the American Heart Association (AHA), omega-3 fatty acids have been shown to benefit the hearts of healthy people and those at high risk of cardiovascular disease. Research indicates that omega-3 fatty acids decrease the risk of arrhythmias, abnormal heartbeats that can lead to sudden death. Omega-3 fatty acids also decrease triglyceride levels.

The U.S. Food and Drug Administration (FDA) in allows foods with omega-3s (such are oily fish) to bear labels indicating that "supportive but not conclusive research shows that consumption of EPA and DHA omega-3 fatty acids may reduce the risk of coronary heart disease."

Sources of essential fatty acids

Omega-3

- Canola oil
- Dark leafy green vegetables (spinach, kale)
- Fatty fish (e.g., salmon, sardines, tuna, mackerel)
- Flaxseed
- Soybean oil
- Walnuts

Omega-6

- Brazil nuts
- Pine nuts
- Safflower oil
- Sunflower oil
- Tahini

Description

Fats are molecules composed of two types of smaller molecules, glycerol and/or fatty acids. The three types of fats in the diet are saturated (including ***trans* fats**), monounsaturated, and polyunsaturated. In addition to serving as a food source, fatty acids are used in cooking and in the manufacture of products such as soaps and cosmetics.

Saturated fats, which are linked to heart disease, are also known as solid fats because they are generally not liquid at room temperature. Saturated fat is found in animal products such as meat and dairy products, including whole milk and full-fat cheese. Other sources of saturated fat include hydrogenated shortening, coconut oil, and palm oils.

Trans fatty acids (*trans* fats) are saturated fats that are formed by hydrogenation, which the addition of hydrogen to vegetable oil. The original fat becomes more saturated and solidifies. This process is used to create foods such as stick margarine and shortening. *Trans* fats are found in some processed foods that use these ingredients, such as cookies and snack foods.

WWW.BOOKBAZ.IR

Unsaturated fats, which are usually liquid at room temperature, are healthier than saturated fats. Monounsaturated fats include canola oil and olive oil, which also contain polyunsaturated fats. The two PUFAs associated with health are omega-3 and omega-6 fatty acids, which may help to counter the effects of saturated fats. Saturated fats promote atherosclerosis, which is known as hardening of the arteries. If cholesterol and other materials build up on the walls of the arteries (blood vessels), they block blood flow, causing the arteries to lose their elasticity. *Trans* fats raise cholesterol levels, especially low-density lipoproteins (LDL) (known as "bad" cholesterol), increasing the risk of heart disease. Omega-3 fatty acids are thought to help lower LDL levels.

Omega fatty acids

The body cannot produce its own fatty acids, but it can convert ALA to EPA and DHA. ALA needs to be obtained from the diet and is essential. The amounts of EPA and DHA produced by the body are minimal, however, so people are advised to obtain them from other sources. Fatty fish such as salmon and albacore tuna are rich in EPA and DHA. The richest source of ALA is flaxseed. Other sources include walnuts, some beans, canola, green leafy vegetables, nuts, and soybeans. Seafood is the best source of omega-3 fats. Although food sources are preferred, omega-3 fatty acids also available in the form of **dietary supplements** that contain flaxseed oil or fish oil.

Specific sources of omega-3s include:

- 3 ounces (oz.) of pickled herring (1.2 grams [g] of omega-3s)
- 3 oz. of salmon (1.3 g)
- 3 oz. of halibut (1.0 g)
- 3 oz. of mackerel (1.6 g)
- 1 1/2 teaspoons (tsp.) of flaxseeds (3 g)

The omega-6 fatty acid linoleic acid (LA) is another essential fatty acid that must be obtained in the diet. It is found in vegetable oils such as safflower, corn, cottonseed, and soybean oils. In the body, LA is converted to gamma-linolenic acid (GLA). It is then broken down to arachidonic acid (AA). In addition to those fatty acids, the body also uses LA to synthesize dihomo-gamma-linolenic acid (DGLA). GLA is also found in plant-based oils such as evening primrose oil, which is sold as a dietary supplement. Some omega-6 fatty acids may promote inflammation, but GLA converted into DGLA in the body may help reduce inflammation.

Ratio of omega-3 to omega-6

Cereals, whole-grain breads, margarine, and vegetable oils such as corn, peanut, and sunflower oil are examples of omega-6 fatty acid sources. People can also obtain omega-6 fatty acids by eating meat from animals fed grains rich in omega-6. There is no set ratio of omega-6s to omega-3s, but according to UMMC, a more preferable ratio ranges from 2:1 to 4:1, and some health educators advocate a lower ratio. Health experts agree that intake of foods containing n-3 fats needs to be increased.

Sources of omega fatty acids

SEAFOOD. The American Heart Association recommends that people consume fish at least twice a week. Preferred sources are fatty fish such as salmon, tuna, albacore tuna, and mackerel. Increased intake of seafood is also recommended in the *Dietary Guidelines for Americans* issued by the U.S. Department of Agriculture (USDA) and the Department of Health and Human Services (HHS). The *Guidelines* advise adults to consume a total of 1,750 mg of EPA and DHA from eating 8 oz. of fish each week. Smaller amounts of seafood are recommended for children.

According to the *Guidelines*, some common seafood varieties and their EPA, DHA, and mercury contents include (per four ounce serving):

- salmon (Atlantic, Chinook, Coho)—1,200–2,400 micrograms (mcg) of EPA/DHA and 2 mcg of mercury
- anchovies, herring, and shad—2,300–2,400 mcg of EPA/DHA and 5–10 mcg of mercury
- mackerel (Atlantic and Pacific)—1,350–2,400 mcg of EPA/DHA and 8–13 mcg of mercury
- tuna (bluefin and albacore)—1,700 mcg of EPA/DHA and 54–58 mcg of mercury
- tuna (canned, light)—150–300 mcg of EPA/DHA and 8–13 mcg of mercury
- oysters (Pacific)—1,550 mcg of EPA/DHA and 2 mcg of mercury
- oysters (Atlantic)—500–550 mcg of EPA/DHA and 2 mcg of mercury

FLAXSEED. Flaxseed is the seed of the plant *Linum usitatissimum*. It is a rich source of ALA and also contains LA. Flaxseed is high in dietary **fiber** and lignans, phytochemicals that mimic the effect of the female hormone estrogen. Flaxseed oil is derived from pressed flaxseed. Flaxseed and flaxseed oil have different properties and nutritional values. According to the Flax Council of Canada, about 42% of the flaxseed is

oil and more than 70% of that oil is polyunsaturated fat (PUFA). Of that fat content, 57% is ALA.

SUPPLEMENTS. Food is the preferred source of nutrients like omega fatty acids, and most people obtain more than an adequate intake of omega-6 fatty acids from food. However, omega fatty acids are also available in the form of dietary supplements. In the United States, omega-fatty acid in forms including fish oil supplements was the top remedy taken for health reasons by adults and children in 2007, according to NCCAM. The fourth top remedy taken by adults and children was flaxseed. Omega-6 fatty acids are present in supplements such as evening primrose oil. The FDA recommends that consumers not take more than a total of 3 g per day of EPA and DHA omega-3 fatty acids, with no more than 2 g per day from a dietary supplement.

Recommended intake

There is no recommended daily allowance (RDA) for polyunsaturated fats, but there are established adequate intake (AI) levels. The daily AI levels for omega-3s are:

- infants 0–6 months: 0.5 g
- infants 7–12 months: 0.5 g
- children 1–3 years: 0.7 g
- children 4–8 years: 1.0 g
- males 9–13 years: 1.2 g
- males 14 and older: 1.6 g
- females 9 and older: 1.1 g
- pregnant women: 1.1 g
- breastfeeding women: 1.3 g

The daily AI levels for omega-6 fats are:

- infants 0–6 months: 4.4 g
- infants 7–12 months: 4.6 g
- children 1–3 years: 7 g
- children 4–8 years: 10 g
- females 9–13 years: 10 g
- males 9–13 years: 12 g
- females 14–18 years: 11 g
- males 14–18 years: 16 g
- females 19–50 years: 12 g
- males 19–50 years: 17 g
- females 51 and older: 11 g
- females 51 and older: 14 g
- pregnant and breastfeeding women: 13 g

The AHA has separate recommendations for people with certain conditions, but individuals should discuss these with their physician. According to the AHA, people with **coronary heart disease** should consume 1 g of omega-3 fatty acids daily through food intake, most preferably fatty fish. People with high **triglycerides** (fatty material that circulates in the blood) may require doses up to 4 g, which may be obtained by taking supplements.

Precautions

People should discuss supplement intake with their physician before adding any supplements to their diet. This is especially important for women who are pregnant or **breastfeeding** and people with chronic conditions such as **cancer**. Although the FDA views omega-3 dietary supplements from fish as "generally recognized as safe (GRAS)," supplements do not undergo the stringent testing for safety and effectiveness that is required for drugs.

Some fish may contain high levels of mercury or other environmental pollutants, polychlorinated biphenyls (PCBs) or dioxins. Fish with the highest levels of mercury include tilefish, shark, swordfish, and king mackerel. Varying seafood choices can help minimize this risk, especially for people who regularly consume fish. Seafood varieties that are lower in mercury include salmon, anchovies, herring, sardines, Pacific oysters, trout, and Atlantic and Pacific mackerel.

Flaxseed, flaxseed oil, and fish and krill oils should be refrigerated to help maintain their effectiveness.

Interactions

People who take medications should consult with their doctors before they start taking any dietary supplements. Omega fatty acid supplements may increase the risk of bleeding in people who take blood thinning medications such as warfarin (Coumadin) or clopidogrel (Plavix). They may also interact with diabetes medications, antibiotics, hormone replacement therapy, and some drugs used in cancer treatment.

Complications

There have been some mixed results in studies that link flax and ALA to certain types of cancers. People diagnosed or at risk for hormone-sensitive breast or uterine cancer (for flax) or prostate cancer (for ALA) should consult with their physicians before taking these supplements. Omega supplements including flaxseed may lower blood sugar levels, which can be particularly dangerous for people with diabetes.

WWW.BOOKBAZ.IR

KEY TERMS

Alpha-linolenic acid (ALA)—A polyunsaturated omega-3 fatty acid found primarily in seed oils (canola oil, flaxseed oil, and walnut oil), purslane and other broad-leaved plants, and soybeans. ALA is thought to lower the risk of cardiovascular disease.

Atherosclerosis—Clogging, narrowing, and hardening of the large arteries and medium-sized blood vessels. Atherosclerosis can lead to stroke, heart attack, eye problems, and kidney problems.

Cardiovascular—Pertaining to the heart and blood vessels.

Cardiovascular disease—Describes medical conditions that relate to disease of the heart and circulatory system (blood vessels), such as angina, heart attacks and strokes.

Cholesterol—A waxy substance made by the liver and also acquired through diet. High levels in the blood may increase the risk of cardiovascular disease.

Dietary supplement—A product, such as a vitamin, mineral, herb, amino acid, or enzyme, that is intended to be consumed in addition to an individual's diet with the expectation that it will improve health.

Docosahexaenoic acid (DHA)—A long-chain omega-3 fatty acid found primarily in oily fish. It is important for the development of the brain and the retina of the eye.

Essential fatty acid—A type of fat that is necessary for the normal function of the brain and body and that the body is unable to produce itself, making them essential to be taken in through diet.

Flaxseed—Linseed; the seed of flax, *Linum usitatissimum*, used as a source of oil for treating inflammation of the respiratory, intestinal, and urinary tracts, and as a dietary supplement.

Monounsaturated fat—A fat or fatty acid with only one double-bonded carbon atom in its molecule. The most common monounsaturated fats are palmitoleic acid and oleic acid. They are found naturally in such foods as nuts and avocados; oleic acid is the main component of olive oil.

Polyunsaturated fat—A fatty acid molecule with two or more double bonds, known to be beneficial to health when consumed in moderate amounts. A type of fat found in some vegetable oils, such as sunflower, safflower, and corn.

The NCCAM cautions that fish oil supplements may cause minor gastrointestinal upsets, including diarrhea, **heartburn**, indigestion, and abdominal bloating.

Research and general acceptance

Studies have shown that regularly consuming fish or fish oil supplements can help lower triglyceride and blood pressure levels, slow the progression of atherosclerosis, and reduce the risk of heart attack, stroke, and death among people with cardiovascular disease. There is also some evidence that consumption of omega-3s by pregnant women, especially DHA, may improve infant health outcomes, especially in relation to visual and cognitive development.

CARDIOVASCULAR RESEARCH. The 1980s *Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardio* study, referred to as the GISSI-Prevenzione Trial, was one of the largest studies of n-3 and cardiovascular health. In the study, 11,324 patients with coronary heart disease were divided into four groups: one group received 300 mg of **vitamin E**, the second received 850 mg of omega-3 fatty acids, the third received the vitamin E and fatty acids, and the fourth served as the control group. After a little more than three years, the second group saw a 45% decrease in instances of sudden death and an overall 20% decline in mortality rates.

Since then, numerous studies have shown that diets rich in omega-3 fatty acids not only lower LDL cholesterol but also triglycerides. Studies of Inuit Eskimos have found their cholesterol levels to be healthy, despite the fact that they consume a high-fat diet. This is thought to be because the traditional Inuit diet is high in fatty fish, which is rich with omega-3 fatty acids. The same has been said about Mediterranean diets.

A large-scale review published in *Mayo Clinic Proceedings* in 2008 cited three controlled trials involving 32,000 participants who either received omega-3 fatty acid supplements containing DHA and EPA or served as controls. The results found decreases in adverse cardiovascular effects by 19–45%.

Furthermore, the effect of fish oil on the potential for irregular heartbeat in older adults was the subject of a longterm study described in the March 2012 issue of *Circulation*, the journal of the American Heart

Association. Heart arrhythmias are caused when electrical impulses cause the heart to beat irregularly, too rapidly, or too slowly. The study focused on atrial fibrillation (AF), which is an irregular and frequently rapid heart rate.

Despite all of the support for omega fatty acids in heart health, a review of 68,680 patients, published in *JAMA* (the Journal of the American Medical Association) in 2012, found no link between omega-3 fatty acid supplementation and lowered cardiovascular risk. Further research is needed.

WEIGHT LOSS RESEARCH. One claim for omega-3 fatty acids is that they promote weight loss in conjunction with a healthy diet. A study published in the February 2011 issue of the *American Journal of Clinical Nutrition* found little difference between weight loss in subjects taking omega-3 supplements and placebo. Evidence did support the use of omega-3 fatty acids in managing triglyceride levels and promoting heart health, however, as well as the notion that omega-3s have anti-inflammatory properties. Omega-3 supplements are thought to be effective in reducing the symptoms associated with rheumatoid arthritis, such as joint tenderness and stiffness. In some cases, a reduction in the amount of medication needed by rheumatoid arthritis patients has been noted.

Parental concerns

Many dietary supplements state that their products are for adults age 18 and older unless the use of supplements is approved by a child's pediatrician or healthcare professional.

Pregnant or breastfeeding women should discuss fish consumption with their physicians due to the risk of mercury consumption.

Onychomycosis

Definition

Onychomycosis is a fungal infection of the fingernails or toenails. The actual infection is of the bed of the nail and of the plate under the surface of the nail.

Description

Onychomycosis is the most common of all diseases of the nails in adults. In North America, the incidence falls roughly between 2% and 13%. The incidence of onychomycosis is also greater in older adults, and up to 90% of the elderly may be affected. Men are more commonly infected than women.

Individuals who are especially susceptible include those with chronic diseases such as diabetes and circulatory problems and those with diseases that suppress the immune system. Other risk factors include a family history, previous **trauma** to the nails, warm climate, and occlusive or tight footwear.

Causes and symptoms

Onychomycosis is caused by three types of fungi: dermatophytes, yeasts, and nondermatophyte molds. Fungi are simple parasitic plant organisms that do not need sunlight to grow. Toenails are especially susceptible because fungi prefer dark damp places. Swimming pools, locker rooms, and showers typically harbor fungi. Chronic diseases such as diabetes, problems with the circulatory system, or immune deficiency disease are risk factors. A history of athlete's foot and excess perspiration are also risk factors.

Onychomycosis can be present for years without causing **pain** or disturbing symptoms. Typically, the nail becomes thicker and changes to a yellowish-brown. Foul-smelling debris may collect under the nail. The infection can spread to the surrounding nails and even the skin.

Diagnosis

To make a diagnosis of onychomycosis, the clinician must collect a specimen of the nail in which infection is suspected. A clipping is taken from the nail plate, and a sample of the debris from underneath the nail bed is also taken, usually with a sharp curette. Debris from the nail surface may also be taken. These will be sent for microscopic analysis to a laboratory, as well as cultured to determine what types of fungus are growing there.

Treatment

Onychomycosis is very difficult and sometimes impossible to treat, and therapy is often long-term. Therapy consists of topical treatments that are applied directly to the nails, as well as two systemic drugs, griseofulvin and ketoconazole. Topical therapy is reserved for only the mildest cases. The use of griseofulvin and ketoconazole is problematic, and there are typically high relapse rates of 50–85%. In addition, treatment must be continued for a long duration (10–18 months for toenails), with monthly laboratory monitoring for several side effects, including liver toxicity. Individuals taking these medications must also abstain from alcohol consumption.

In the past few years, newer oral antifungal agents have been developed, and include itraconazole (Sporanox), terbinafine (Lamisil), and fluconazole (Diflucan). These agents, when taken orally for as little as 12 weeks, bring about better cure rates and fewer side effects than either griseofulvin or ketoconazole. The most common side effect is stomach upset. Patients taking oral antifungal therapy must have a **complete blood count** and liver enzyme workup every four to six weeks. Terbinafine in particular has markedly less toxicity to the liver, one of the more severe side effects of the older agents, griseofulvin and ketoconazole.

Treatment should be continued until microscopic exam or culture shows no more fungal infection. Nails may, however, continue to look damaged even after a clinical cure is achieved. Nails may take up to a full year to return to normal. If the nail growth slows or stops, additional doses of antifungal therapy should be taken.

Nail **debridement** is another treatment option, but it is considered by many to be primitive compared with topical or systemic treatment. Clinicians perform nail debridement in their offices. The nail is cut and then thinned using surgical tools or chemicals, and then the loose debris under the nail is removed. The procedure is painless, and often improves the appearance of the nails immediately. In addition, it helps whatever medication being used to penetrate the newly thinned nail. Patients with very thickened nails will sometimes undergo chemical removal of a nail. A combination of oral, topical, and surgical removal can increase the chances of curing the infection.

Alternatives

For controlling onychomycosis, as opposed to curing it, some experts advocate using Lotrimin cream, available over the counter. The cream should be thoroughly rubbed into the nail daily in order to control the infection.

WWW.BOOKBAZ.IR

KEY TERMS

Curette—Spoon-shaped instrument for removing debris, growths, or infected nail matter.

Dermatophytes, yeasts, and nondermatophyte molds—Three types of fungi responsible for fungal infections of the nails.

In general, **nutrition** may also play a role in promoting good nail health and thus preventing nail disease. Adequate protein and **minerals**, in the form of nuts, seeds, whole grains, legumes, fresh vegetables, and fish, should be consumed. Sugars, alcohol, and **caffeine** should be avoided. Certain supplements may also be beneficial, including **vitamin A** (10,000 IU per day), zinc (15–30 mg per day), iron (ferrous glycinate 100 mg per day, vitamin B_{12} (1,000 mcg per day), and essential fatty acids in the form of flax, borage, or evening primrose oil (1,000–1,5000 mg twice daily).

Herbal remedies may also relieve some of the symptoms of onychomycosis. A combination of coneflower, oregano, spilanthes, usnea, Oregon grape root, and myrrh can be used as a tincture (20 drops four times daily).

Undiluted grapefruit seed extract and tea tree oil are also said to be beneficial when applied topically to the infected nails.

Prognosis

Onychomycosis is typically quite difficult to cure completely. Even if a clinical cure is achieved after long therapy with either topical or oral drugs, normal regrowth takes four to six months in the fingernails, and eight to 12 months in the toenails, which grow more slowly. Relapse is common, and often, the nail or nail bed is permanently damaged. For toenails infected with onychomycosis, terbinafine seems to offer the highest cure rate (35–50%). Itraconazole cure rates typically range from 25–40%, and those with fluconazole, which was recently approved in the United States, have not been documented by long-term trials

Prevention

Keeping the feet clean and dry, and washing with soap and water and drying thoroughly are important preventive steps to take to prevent onychomycosis. Other preventive measures include keeping the nails cut short and wearing shower shoes whenever walking or showering in public places. Daily changes of shoes, socks, or hosiery are also helpful. Excessively tight hose or shoes promote moisture, which in turn, provides a wonderful environment for onychomycotic infections. To prevent this, individuals should wear only socks made of synthetic fibers, which can absorb moisture more quickly than those made of cotton or wools. Manicure and pedicure tools should be disinfected after each use. Finally, nail polish should not be applied to nails that are infected, as this causes the water or moisture that collects under the surface of the nail to not evaporate and be trapped.

Oophorectomy

Definition

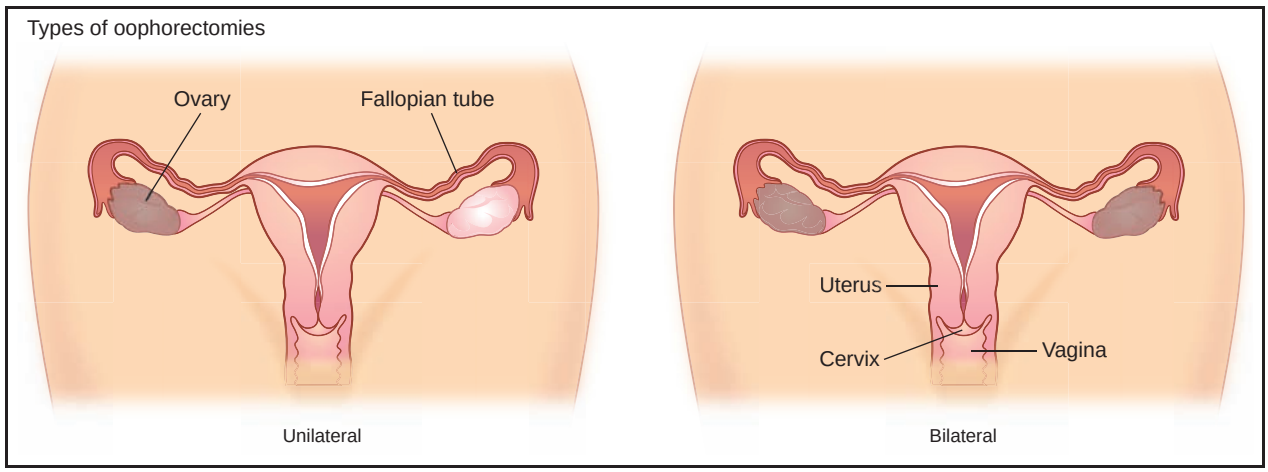
Unilateral oophorectomy (also called an ovariectomy) is the surgical removal of an ovary. If one ovary is removed, a woman may continue to menstruate and have children. If both ovaries are removed, a procedure called a bilateral oophorectomy, menstruation stops and a woman loses the ability to have children.

Purpose

Oophorectomy is performed to:

- remove cancerous ovaries
- remove the source of estrogen that stimulates some cancers
- remove a large ovarian cyst
- excise an abscess
- treat endometriosis

In an oophorectomy, one or a portion of one ovary may be removed or both ovaries may be removed.



In a unilateral oophorectomy, just one ovary is removed; in a bilateral oophorectomy, both ovaries are removed. *(Illustration by Electronic Illustrators Group. Copyright © 2014 Cengage Learning®.)*

When an oophorectomy is done to treat **ovarian cancer** or other spreading cancers, both ovaries are removed (called a bilateral oophorectomy). Removal of the ovaries and fallopian tubes is performed in about one-third of hysterectomies (surgical removal of the uterus), often to reduce the risk of ovarian cancer.

Oophorectomies are sometimes performed on premenopausal women who have estrogen-sensitive **breast cancer** in an effort to remove the main source of estrogen from their bodies. This procedure has become less common than it was in the 1990s. Today, **chemotherapy** drugs are available that alter the production of estrogen and tamoxifen blocks any of the effects any remaining estrogen may have on cancer cells.

Until the 1980s, women over age 40 having hysterectomies routinely had healthy ovaries and fallopian tubes removed at the same time. This operation is called a bilateral **salpingo-oophorectomy**. Many physicians reasoned that a woman over 40 was approaching **menopause** and soon her ovaries would stop secreting estrogen and releasing eggs. Removing the ovaries would eliminate the risk of ovarian cancer and only accelerate menopause by a few years.

In the 1990s, the thinking about routine oophorectomy began to change. The risk of ovarian cancer in women who have no family history of the disease is less than 1%. Meanwhile, removing the ovaries increases the risk of cardiovascular disease and accelerates **osteoporosis** unless a woman takes prescribed hormone replacements.

Under certain circumstances, oophorectomy may still be the treatment of choice to prevent breast and ovarian cancer in certain high-risk women. A study done at the University of Pennsylvania and released in 2000 showed that healthy women who carried the BRCA1 or BRCA2 genetic mutations that pre-disposed them to breast cancer had their risk of breast cancer drop from 80% to 19% when their ovaries were removed before age 40. Women between the ages of 40 and 50 showed less risk reduction, and there was no significant reduction of breast cancer risk in women over age 50. A 2002 study showed that five years after being identified as carrying BRCA1 or BRCA2 genetic mutations, 94% of women who had received a bilateral salpingo-oophorectomy were cancer-free, compared to 79% of women who had not received surgery.

The value of ovary removal in preventing both breast and ovarian cancer has been documented. However, there are disagreements within the medical community about when and at what age this treatment should be offered. Preventative oophorectomy, also called prophylactic oophorectomy, is not always covered by insurance. One study conducted in 2000 at the University of California at San Francisco found that only 20% of insurers paid for preventive bilateral oophorectomy (PBO). Another 25% had a policy against paying for the operation, and the remaining 55% said that they would decide about payment on an individual basis.

Demographics

Overall, ovarian cancer accounts for only 4% of all cancers in women. But the lifetime risk for developing ovarian cancer in women who have mutations in BRCA1 is significantly increased over the general population and may cause an ovarian cancer risk of 30% by age 60. For women at increased risk,

WWW.BOOKBAZ.IR

KEY TERMS

Cyst—An abnormal sac containing fluid or semi-solid material.

Endometriosis—A benign condition that occurs when cells from the lining of the uterus begin growing outside the uterus.

Fallopian tubes—Slender tubes that carry ova from the ovaries to the uterus.

Hysterectomy—Surgical removal of the uterus.

Osteoporosis—The excessive loss of calcium from the bones, causing the bones to become fragile and break easily.

oophorectomy may be considered after the age of 35 if childbearing is complete.

Other factors that increase a woman's risk of developing ovarian cancer include age (most ovarian cancers occur after menopause), the number of menstrual periods a woman has had (affected by age of onset, **pregnancy**, breastfeeding, and oral contraceptive use), history of breast cancer, diet, and family history. The incidence of ovarian cancer is highest among Native Americans (17.5 cases per 100,000 population), white (15.8 per 100,000), Vietnamese (13.8 per 100,000), white Hispanic (12.1 per 100,000), and Hawaiian (11.8 per 100,000) women; it is lowest among Korean (7.0 per 100,000) and Chinese (9.3 per 100,000) women. African American women have an ovarian cancer incidence of 10.2 per 100,000 population.

Description

Oophorectomies are usually performed in a hospital operating room by a gynecologist, a medical doctor who has completed specialized training in the areas of women's general health, pregnancy, labor and **childbirth**, prenatal testing, and genetics.

Oophorectomy is done under general or regional **anesthesia**. It is often performed through the same type of incision, either vertical or horizontal, as an abdominal **hysterectomy**. Horizontal incisions leave a less noticeable scar, but vertical incisions give the surgeon a better view of the abdominal cavity. After the incision is made, the abdominal muscles are stretched apart, not cut, so that the surgeon can see the ovaries. Then the ovaries, and often the fallopian tubes, are removed.

Oophorectomy can sometimes be done with a laparoscopic procedure. With this surgery, a tube containing a tiny lens and light source is inserted through a small incision in the navel. A camera can be attached that allows the surgeon to see the abdominal cavity on a video monitor. When the ovaries are detached, they are removed though a small incision at the top of the vagina. The ovaries can also be cut into smaller sections and removed.

The advantages of abdominal incision are that the ovaries can be removed even if a woman has many **adhesions** from previous surgery. The surgeon gets a good view of the abdominal cavity and can check the surrounding tissue for disease. A vertical abdominal incision is mandatory if cancer is suspected. The disadvantages are that bleeding is more likely to be a complication of this type of operation. The operation is more painful than a laparoscopic operation and the recovery period is longer. A woman can expect to be in the hospital two to five days and will need three to six weeks to return to normal activities.

Preparation

Before surgery, the doctor will order blood and urine tests, and any additional tests such as **ultrasound** or x rays to help the surgeon visualize the woman's condition. The woman may also meet with the anesthesiologist to evaluate any special conditions that might affect the administration of anesthesia. A colon preparation may be done, if extensive surgery is anticipated.

On the evening before the operation, the woman should eat a light dinner, then take nothing by mouth, including water or other liquids, after midnight.

Aftercare

After surgery a woman will feel discomfort. The degree of discomfort varies and is generally greatest with abdominal incisions, because the abdominal muscles must be stretched out of the way so that the surgeon can reach the ovaries. In order to minimize the risk of postoperative infection, **antibiotics** will be given.

When both ovaries are removed, women who do not have cancer are started on **hormone replacement therapy** to ease the symptoms of menopause that occur because estrogen produced by the ovaries is no longer present. If even part of one ovary remains, it will produce enough estrogen that a woman will continue to menstruate, unless her uterus was removed in a hysterectomy. To help offset the higher risks of heart and bone disease after loss of the ovaries, women should get plenty of **exercise**, maintain a low-fat diet, and ensure intake of **calcium** is adequate.

Return to normal activities takes anywhere from two to six weeks, depending on the type of surgery. When women have cancer, chemotherapy or radiation are often given in addition to surgery. Some women have emotional **trauma** following an oophorectomy, and can benefit from counseling and support groups.

Results

If the surgery is successful, the ovaries will be removed without complication, and the underlying problem resolved. In the case of cancer, all the cancer will be removed. A woman will become infertile following a bilateral oophorectomy.

Morbidity and mortality rates

Studies have shown that the complication rate following oophorectomy is essentially the same as that following hysterectomy. The rate of complications associated with hysterectomy differs by the procedure performed. Abdominal hysterectomy is associated with a higher rate of complications (9.3%), while the overall complication rate for vaginal hysterectomy is 5.3%, and 3.6% for laparoscopic vaginal hysterectomy. The risk of death is about one in every 1,000 women having a hysterectomy. The rates of some of the more commonly reported complications are:

- excessive bleeding (hemorrhaging): 1.8–3.4%
- fever or infection: 0.8–4.0%
- accidental injury to another organ or structure: 1.5–1.8%

Because of the cessation of hormone production that occurs with a bilateral oophorectomy, women who lose both ovaries also prematurely lose the protection these hormones provide against **heart disease** and osteoporosis. Women who have undergone bilateral oophorectomy are seven times more likely to develop coronary heart disease and much more likely to develop bone problems at an early age than are premenopausal women whose ovaries are intact.

Risks

Oophorectomy is a relatively safe operation, although, like all major surgery, it does carry some risks. These include an unanticipated reaction to anesthesia, internal bleeding, **blood clots**, accidental damage to other organs, and post-surgery infection.

Complications after an oophorectomy include changes in sex drive, hot flashes, and other symptoms of menopause if both ovaries are removed. Women who have both ovaries removed and who do not take estrogen replacement therapy run an increased risk for cardiovascular disease and osteoporosis. Women with a history of psychological and emotional problems before an oophorectomy are more likely to experience psychological difficulties after the operation.

Complications may arise if the surgeon finds that cancer has spread to other places in the abdomen. If the cancer cannot be removed by surgery, it must be treated with chemotherapy and radiation.

Alternatives

Depending on the specific condition that warrants an oophorectomy, it may be possible to modify the surgery so at least a portion of one ovary remains, allowing the woman to avoid early menopause. In the case of prophylactic oophorectomy, drugs such as tamoxifen may be administered to block the effects that estrogen may have on cancer cells.

Ophthalmic antibiotics *see* **Antibiotics, ophthalmic**

Ophthalmoplegia

Definition

Ophthalmoplegia is a **paralysis** or weakness of one or more of the muscles that control eye movement. The condition can be caused by any of several neurologic disorders. It may be myopathic, meaning that the muscles controlling eye movement are directly involved, or neurogenic, meaning that the nerve pathways controlling eye muscles are affected. Diseases associated with ophthalmoplegia are ocular myopathy, which affects muscles, and internuclear ophthalmoplegia, a disorder caused by **multiple sclerosis**, a disease which affects nerves.

Description

Because the eyes do not move together in ophthalmoplegia, patients may complain of double vision. Double vision is especially troublesome if the ophthalmoplegia comes on suddenly or affects each eye differently. Because ophthalmoplegia is caused by another, underlying disease, it is often associated with other neurologic symptoms, including limb weakness, lack of coordination, and numbness.

Causes and symptoms

Ocular myopathy is also known as mitochondrial encephalomyelopathy with ophthalmoplegia or progressive external ophthalmoplegia. Because it is so often associated with diseases affecting many levels of the neurologic system, it is often referred to as "ophthalmoplegia plus." The main feature is progressive limitation of eye movements, usually with drooping of the eyelids (**ptosis**). Ptosis may occur years before other symptoms of ophthalmoplegia. Because both eyes are equally involved and because ability to move the eyes lessens gradually over the course of years, double vision is rare. On examination, the eyelids may appear thin. This disease usually begins in childhood or adolescence but may start later.

When ophthalmoplegia is caused by muscle degeneration (myopathic), muscle biopsy, in which a small piece of muscle is surgically removed and examined microscopically, will find characteristic abnormal muscle fibers called ragged red fibers. In this form of ophthalmoplegia, the patient may experience weakness of the face, the muscles involved in swallowing, the neck, or the limbs.

Progressive external ophthalmoplegia is sometimes associated with specific neurologic syndromes. These syndromes include familial forms of spastic paraplegia, spinocerebellar disorders, or sensorimotor **peripheral neuropathy**. Kearns-Sayre syndrome causes ophthalmoplegia along with loss of pigment in the retina, the light-sensitive membrane lining the eye. In addition, the disease may cause **heart block** that must be corrected with a pacemaker, increased protein in the cerebrospinal fluid, and a progressively disabling lack of muscular coordination (cerebellar syndrome). Symptoms of the disease appear before age 15.

Some of the progressive external ophthalmoplegia syndromes are unusual in that inheritance is controlled by DNA in the mitochondria. The mitochondria are rod-shaped structures within a cell that convert food to usable energy. Most inherited diseases are passed on by DNA in the cell nucleus, the core that contains the hereditary material. Mitochondrial inheritance tends to be passed on by the mother. Other forms of progressive external ophthalmoplegia are not inherited but occur sporadically with no clear family history. It is not known why some forms are neurogenic and others are myopathic. In the forms inherited through mitochondrial DNA, it is not known which gene product is affected.

Internuclear ophthalmoplegia in multiple sclerosis is caused by damage to a bundle of fibers in the brainstem called the medial longitudinal fasciculus. In this syndrome, the eye on the same side as the damaged medial longitudinal fasciculus is unable to look outward (that is, the left eye cannot look left). The other eye exhibits jerking movements (**nystagmus**) when the patient tries to look left. Internuclear ophthalmoplegia may be seen rarely without multiple sclerosis in patients with certain types of cancer or with Chiari type II malformation.

Eye **movement disorders** and ophthalmoplegia can also be seen with **progressive supranuclear palsy**, thyroid disease, **diabetes mellitus**, brainstem tumors, migraine, basilar artery **stroke**, pituitary stroke, **myasthenia gravis**, **muscular dystrophy**, and the Fisher variant of Guillain-Barré syndrome. A tumor or aneurysm in the cavernous sinus, located behind the eyes, can cause painful ophthalmoplegia. Painful ophthalmoplegia can also be caused by an

KEY TERMS

Cerebellar—Involving the cerebellum, which controls walking, balance, and coordination.

Cerebrospinal fluid—Fluid bathing the brain and spinal cord.

Heart block—A problem with electrical conduction in the heart muscle that may lead to irregular heartbeat and require a pacemaker for treatment.

Mitochondria—Spherical or rod shaped parts of the cell. Mitochondria contain genetic material (DNA and RNA) and are responsible for converting food to energy.

inflammatory process, called Tolosa-Hunt syndrome,in the same area.

Diagnosis

The patient's medical and family history and the examination findings will usually help differentiate the various syndromes associated with ophthalmoplegia. In addition, each syndrome is associated with characteristic features, such as nystagmus or ptosis. All patients with progressive external ophthalmoplegia should have a muscle biopsy to look for ragged red fibers or changes suggesting muscular dystrophy. A sample should be sent for analysis of mitochondrial DNA. Electromyogram (EMG), measurement of electrical activity in the muscle, helps diagnose myopathy.

Computed tomography scan (CT scan) or **magnetic resonance imaging** (MRI) scans of the brain may be needed to rule out **brain tumor**, stroke, aneurysm, or multiple sclerosis. When multiple sclerosis is suspected, evoked potential testing of nerve response may also be helpful. Analysis of cerebrospinal fluid may show changes characteristic of multiple sclerosis or Kearns-Sayre syndrome. Other tests that may be helpful in Kearns-Sayre include electrocardiogram (measuring electrical activity of the heart muscles), retinal examination, and a hearing test (audiogram). For possible myasthenia gravis, the Tensilon (edrophonium) test should be done. Tests should also be done to measure activity of the cell-surface receptors for acetylcholine, a chemical that helps pass electrical impulses along nerve cells in the muscles. Thyroid disease and diabetes mellitus should be excluded by appropriate blood work.

Treatment

There are no specific cures for ocular myopathy or progressive external ophthalmoplegia. **Vitamin E** therapy has been used to treat Kearns-Sayre syndrome. Coenzyme Q (ubiquinone), a naturally occurring substance similar to **vitamin K**, is widely used to treat other forms of progressive external ophthalmoplegia, but the degree of success varies. Specific treatments are available for multiple sclerosis, myasthenia gravis, diabetes mellitus, and thyroid disease. Symptoms of ophthalmoplegia can be relieved by mechanical treatment. Surgical procedures can lift drooping eyelids or a patch over one eye can be used to relieve double vision. Because there is no blink response, a surgically lifted eyelid exposes the cornea of the eye so that it may become dry or be scratched. These complications must be avoided by using artificial tears and wearing eyepatches at night. In Kearns-Sayre syndrome, a pacemaker may be needed.

Prognosis

The prognosis of progressive external ophthalmoplegia depends on the associated neurological problems; in particular, whether there is severe limb weakness or cerebellar symptoms that may be mild or disabling. As with most chronic neurologic diseases, mortality increases with disability. Progressive external ophthalmoplegia itself is not a life-threatening condition. Kearns-Sayre syndrome is disabling, probably shortens the life span, and few if any patients have children. Overall life expectancy for multiple sclerosis patients is seven years less than normal; death rates are higher for women than for men.

Prevention

There is no way to prevent ophthalmoplegia.

Oppositional defiant disorder

Definition

Oppositional defiant disorder (ODD) is defined by the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), as a recurring pattern of negative, hostile, disobedient, and defiant behavior in a child or adolescent, lasting for at least six months without serious violation of the basic rights of others. The incidence of ODD in the U.S. population varies somewhat according to the sample studied; the American Academy of Child and Adolescent Psychiatry (AACAP) gives a figure of 1–6%.

Description

In order to meet DSM-5 criteria for ODD, the behavior disturbances must cause clinically significant problems in social, school, or work functioning. The course of oppositional defiant disorder varies among patients. In males, the disorder is more common among those who had problem temperaments or high motor activity in the preschool years. During the school years, patients may have low self-esteem, changing moods, and a low frustration tolerance. Patients may swear and use alcohol, tobacco, or illicit drugs at an early age. There are frequent conflicts with parents, teachers, and peers.

Children with this disorder show their negative and defiant behaviors by being persistently stubborn and resisting directions. They may be unwilling to compromise, give in, or negotiate with adults. Patients may deliberately or persistently test limits, ignore orders, argue, and fail to accept blame for misdeeds. Hostility is directed at adults or peers and is shown by verbal aggression or deliberately annoying others.

Causes and symptoms

Oppositional defiant disorder is more common in boys than girls before **puberty**; the disorder typically begins by age eight. After puberty the male:female ratio is about 1:1. Although the specific causes of the disorder are unknown, parents who are overly concerned with power and control may cause an eruption to occur. Symptoms often appear at home, but over time may appear in other settings as well. Usually the disorder occurs gradually over months or years. Several theories about the causes of oppositional defiant disorder are being investigated. Oppositional defiant disorder may be related to:

- the child's temperament and the family's response to that temperament
- an inherited predisposition to the disorder in some families
- marital discord or violence between husband and wife
- frequent or multiple geographical moves
- a neurological cause, like a head injury
- a chemical imbalance in the brain (especially with the brain chemical serotonin)

Oppositional defiant disorder appears to be more common in families where at least one parent has a history of a mood disorder, **conduct disorder**, attention deficit hyperactivity disorder, antisocial personality disorder, or a substance-related disorder. Additionally, some studies suggest that mothers with a depressive disorder are more likely to have children with oppositional behavior. However, it is unclear to what extent the mother's depression results from or causes oppositional behavior in children.

Symptoms include a pattern of negative, hostile, and defiant behavior lasting at least six months. During this time four or more specific behaviors must be present. These behaviors include the child who:

- often loses his/her temper
- often argues with adults
- often actively defies or refuses to comply with adults' requests or rules
- often deliberately annoys people
- often blames others for his/her mistakes or misbehavior
- is often touchy or easily annoyed by others
- is often angry and resentful
- is often spiteful or vindictive
- misbehaves
- swears or uses obscene language
- has a low opinion of him/herself

The diagnosis of oppositional defiant disorder is not made if the symptoms occur exclusively in psychotic or **mood disorders**. Criteria are not met for conduct disorder, and, if the child is 18 years old or older, criteria are not met for antisocial personality disorder. In other words, a child with oppositional defiant disorder does not show serious aggressive behaviors or exhibit the physical cruelty that is common in other disorders.

Additional problems may be present, including:

- learning problems

- a depressed mood
- hyperactivity (although attention deficit hyperactivity disorder must be ruled out)
- substance abuse or dependence
- dramatic and erratic behavior

The patient with oppositional defiant disorder is moody, easily frustrated, and may abuse drugs.

Diagnosis

While psychological testing may be needed, the doctor must examine and talk with the child, talk with the parents, and review the medical history. Diagnosis is complicated because oppositional defiant disorder rarely travels alone. Children with attention deficit hyperactivity disorder will also have oppositional defiant disorder 50% of the time. Children with depression/anxiety will have oppositional defiant disorder 10–29% of the time. Because all of the features of this disorder are usually present in conduct disorder, oppositional defiant disorder is not diagnosed if the criteria are met for conduct disorder.

A diagnosis of oppositional defiant disorder should be considered only if the behaviors occur more frequently and have more serious consequences than is typically observed in other children of a similar developmental stage. Further, the behavior must lead to significant impairment in social, school, or work functioning.

A new evaluation scale known as the Oppositional Defiant Behavior Inventory (ODBI) has been developed as an aid to diagnosis. The ODBI appears to meet accepted standards of reliability and validity.

Treatment

Treatment of oppositional defiant disorder usually consists of group, individual and/or **family therapy**, and education. Of these, individual therapy is the most common. Therapy can provide a consistent daily schedule, support, consistent rules, discipline, and limits. It can also help train patients to get along with others and modify behaviors. Therapy can occur in residential, day treatment, or medical settings. Additionally, having a healthy role model as an example is important for the patient.

Parent management training focuses on teaching the parents specific and more effective techniques for handling the child's opposition and defiance. Research has shown that parent management training is more effective than family therapy. One variation of parent management training known as parent-child interaction therapy (PCIT) appears to be helpful over the long term; a group of Australian researchers reported in 2004 that families who were given a course of PCIT maintained their gains two years after the program ended.

KEY TERMS

Attention deficit hyperactivity disorder—A persistent pattern of inattention, hyperactivity and/or impulsiveness; the pattern is more frequent and severe than is typically observed in people at a similar level of development.

Conduct disorder—A repetitive and persistent pattern of behavior in which the basic rights of others are violated or major age-appropriate rules of society are broken.

As of the early 2000s, elementary school teachers were being trained to deal more effectively with classroom disruptions caused by children with ODD. The long-term effectiveness of these interventions, however, will require further study.

Whether involved in therapy or working on this disorder at home, the patient must work with his or her parents' guidance to make the fullest possible recovery. According to the New York Hospital/Cornell Medical Center, the patients must:

- use self timeouts
- identify what increases anxiety
- talk about feelings instead of acting on them
- find and use ways to calm themselves
- frequently remind themselves of their goals
- get involved in tasks and physical activities that provide a healthy outlet for energy
- learn how to talk with others
- develop a predictable, consistent, daily schedule of activity
- develop ways to obtain pleasure and feel good
- learn how to get along with other people
- find ways to limit stimulation
- learn to admit mistakes in a matter-of-fact way

Stimulant medication is used only when oppositional defiant disorder coexists with attention-deficit hyperactivity disorder. Currently, no research iscurrently available on the use of other

WWW.BOOKBAZ.IR

psychiatric medications in the treatment of oppositional defiant disorder.

Prognosis

The outcome varies. In some children the disorder evolves into a conduct disorder or a mood disorder. Later in life, oppositional defiant disorder can develop into passive aggressive personality disorder or antisocial personality disorder. Some children respond well to treatment and some do not. Generally, with treatment, reasonable adjustment in social settings and in the workplace can be made in adulthood.

Optic atrophy

Definition

Optic atrophy can be defined as damage to the optic nerve resulting in a degeneration or destruction of the optic nerve. Optic atrophy may also be referred to as optic nerve head pallor because of the pale appearance of the optic nerve head as seen at the back of the eye. Possible causes of optic atrophy include: **optic neuritis**, Leber's hereditary optic atrophy, toxic or nutritional optic neuropathy, **glaucoma**, vascular disorders, **trauma**, and other systemic disorders.

Description

The process of vision involves light entering the eye and triggering chemical changes in the retina, a pigmented layer lining the back of the eye. Nerve impulses created by this process travel to the brain via the optic nerve. Using a hand-held instrument called an ophthalmoscope, the doctor can see the optic nerve head (optic disc) which is the part of the optic nerve that enters at the back of the eyeball. In optic atrophy, the disc is pale and has fewer blood vessels than normal.

Causes and symptoms

Symptoms of optic atrophy are a change in the optic disc and a decrease in visual function. This change in visual function can be a decrease in sharpness and clarity of vision (visual acuity) or decreases in side (peripheral) vision. Color vision and contrast sensitivity can also be affected.

There are many possible causes of optic atrophy. The causes can range from trauma to systemic disorders. Some possible causes of optic atrophy include:

- Optic neuritis. Optic neuritis is an inflammation of the optic nerve. It may be associated with eye pain worsened by eye movement. It is more common in young to middle-aged women. Some patients with optic neuritis may develop multiple sclerosis later on in life.
- Leber's hereditary optic neuropathy. This is a disease of young men (late teens, early 20s), characterized by an onset over a few weeks of painless, severe, central visual loss in one eye, followed weeks or months later by the same process in the other eye. At first the optic disc may be slightly swollen, but eventually there is optic atrophy. The visual loss is generally permanent. This condition is hereditary. If a patient knows that Leber's runs in the family, genetic counseling should be considered.

- Toxic optic neuropathy. Nutritional deficiencies and poisons can be associated with gradual vision loss and optic atrophy, or with sudden vision loss and optic disc swelling. Toxic and nutritional optic neuropathies are uncommon in the United States, but took on epidemic proportions in Cuba in 1992–1993. The most common toxic optic neuropathy is known as tobacco-alcohol amblyopia, thought to be caused by exposure to cyanide from tobacco smoking, and by low levels of vitamin B_{12} because of poor nutrition and poor absorption associated with drinking alcohol. Other possible toxins included ethambutol, methyl alcohol (moonshine), ethylene glycol (antifreeze), cyanide, lead, and carbon monoxide. Certain medications have also been implicated. Nutritional optic neuropathy may be caused by deficiencies of protein, or of the B vitamins and folate, associated with starvation, malabsorption, or alcoholism.
- Glaucoma. Glaucoma may be caused by an increase of pressure inside the eye. This increased pressure may eventually affect the optic nerve if left untreated.
- Compressive optic neuropathy. This is the result of a tumor or other lesion putting pressure on the optic nerve. Another possible cause is enlargement of muscles involved in eye movement seen in hyperthyroidism (Graves' disease).
- Retinitis pigmentosa. This is a hereditary ocular disorder.
- Syphilis. Left untreated, this disease may result in optic atrophy.

Diagnosis

Diagnosis involves recognizing the characteristic changes in the optic disc with an ophthalmoscope, and measuring visual acuity, usually with an eye chart. Visual field testing can test peripheral vision. Color vision and contrast sensitivity can also be tested. Family history is important in the diagnosis of inherited conditions. Exposure to poisons, drugs, and even medications should be determined. Suspected **poisoning** can be confirmed through blood and urine analysis, as can vitamin deficiency.

Brain **magnetic resonance imaging** (MRI) may show a tumor or other structure putting pressure on the optic nerve, or may show plaques characteristic of **multiple sclerosis**, which is frequently associated with optic neuritis. However, similar MRI lesions may appear in Leber's hereditary optic neuropathy. Mitochondrial DNA testing can be done on a blood sample, and can identify the mutation responsible for Leber's.

Visual evoked potentials (VEP), which measure speed of conduction over the nerve pathways involved in sight, may detect abnormalities in the clinically unaffected eye in early cases of Leber's. Fluorescein **angiography** gives more detail about blood vessels in the retina.

KEY TERMS

Atrophy—A destruction or dying of cells, tissues, or organs.

Cerebellar—Involving the part of the brain (cerebellum), which controls walking, balance, and coordination.

Mitochondia—A structure in the cell responsible for producing energy. A defect in the DNA in the mitochondria is involved in Leber's optic neuropathy.

Neuritis—An inflammation of the nerves.

Neuropathy—A disturbance of the nerves, not caused by an inflammation. For example, the cause may be toxins, or unknown.

Treatment

Treatment of optic neuritis with **steroids** is controversial. There is no known treatment for Leber's hereditary optic neuropathy. Treatment of other causes of optic atrophy varies depending upon the underlying disease.

Prognosis

Many patients with optic neuritis eventually develop multiple sclerosis. Most patients have a gradual recovery of vision after a single episode of optic neuritis, even without treatment. Prognosis for visual improvement in Leber's hereditary optic neuropathy is poor, with the specific rate highly dependent on which mitochondrial DNA mutation is present. If the cause of toxic or nutritional deficiency optic neuropathy can be found and treated early, such as stopping **smoking** and taking **vitamins** in tobacco-alcohol **amblyopia**, vision generally returns to near normal over several months' time. However, visual loss is often permanent in cases of long-standing toxic or nutritional deficiency optic neuropathy.

Prevention

People noticing a decrease in vision (central and/or side vision) should ask their eye care practitioner for a check up. Patients should also go for regular vision exams. Patients should ask their doctor how often that should be, as certain conditons may warrant

WWW.BOOKBAZ.IR

more frequent exams. Early detection of inflammations or other problems lessens the chance of developing optic atrophy.

There are no preventive measures that can definitely abort Leber's hereditary optic neuropathy in those genetically at risk, or in those at risk based on earlier involvement of one eye. However, some doctors recommend that their patients take vitamin C, **vitamin E**, coenzyme Q_{10}, or other **antioxidants**, and that they avoid the use of tobacco or alcohol. Patients should ask their doctors about the use of vitamins. Avoiding toxin exposure and nutritional deficiency should prevent toxic or nutritional deficiency optic neuropathy.

Laurie Barclay, MD

Optic neuritis

Definition

Optic neuritis is a vision disorder characterized by inflammation of the optic nerve.

Description

Optic neuritis occurs when the optic nerve, the pathway that transmits visual information to the brain, becomes inflamed and the myelin sheath that surrounds the nerve is destroyed (a process known as demyelination). It typically occurs in one eye at a time (70%), and the resulting vision loss is rapid and progressive, but only temporary. Thirty percent of patients experience occurrence in both eyes. Optic neuritis tends to afflict young adults with an average age in their 30s. Seventy-five percent of patients with optic neuritis are women.

Nerve damage that occurs in the section of the optic nerve located behind the eyeball, is called *retrobulbar neuritis*, and is most often associated with **multiple sclerosis**. Optic nerve inflammation and **edema** (swelling) caused by intracranial pressure at the place where the nerve enters the eyeball is termed *papillitis*.

Causes and symptoms

Symptoms of optic neuritis include one or more of the following:

- blurred or dimmed vision
- blind spots, particularly with central vision
- pain with eye movement
- headache
- sudden color blindness
- impaired night vision
- impaired contrast sensitivity

Optic neuritis is most commonly associated with multiple sclerosis (MS). Other causes include viral or **fungal infections**, encephalomyelitis, autoimmune diseases, or pressure on the nerve from tumors or vascular diseases (i.e., **temporal arteritis**). Some toxins, such as methanol and lead, can also damage the optic nerve, as can long-term abuse of alcohol and tobacco. Patients with non-MS related optic neuritis are usually immunocompromised in some way.

Diagnosis

An ophthalmologist, a physician trained in diseases of the eye, will typically make a diagnosis of optic neuritis. A complete visual exam, including a visual acuity test, color vision test, and examination of the retina and optic disc with an ophthalmoscope, will be performed. Clinical signs such as impaired pupil response may be apparent during an eye exam, but in some cases the eye may appear normal. A medical history will also be performed to determine if exposure to toxins such as lead may have caused the optic neuritis.

Further diagnostic testing such as **magnetic resonance imaging** (MRI) may be necessary to confirm a diagnosis of optic neuritis. An MRI can also reveal signs of multiple sclerosis.

Treatment

Treatment of optic neuritis depends on the underlying cause of the condition. Vision loss resulting from a viral condition usually resolves itself once the virus is treated, and optic neuritis resulting from toxin damage may improve once the source of the toxin is removed.

A course of intravenous **corticosteroids** (**steroids**) followed by oral steroids has been found to be helpful in restoring vision quickly to patients with MS-related episodes of optic neuritis, but its efficacy in preventing relapse is debatable. The Optic Neuritis Treatment

KEY TERMS

Atrophy—Cell wasting or death.

Multiple sclerosis—An autoimmune disease of the central nervous system characterized by damage to the myelin sheath that covers nerves.

Temporal arteritis—Also known as giant cell arteritis. Inflammation of the large arteries located in the temples which is marked by the presence of giant cells and symptoms of headache and facial pain.

Visual acuity test—An eye examination that determines sharpness of vision, typically performed by identifying objects and/or letters on an eye chart.

Trial (ONTT) has shown that IV steroids may be effective in reducing the onset of MS for up to two years, but further studies are necessary. Oral prednisone has been found to increase the likelihood of recurrent episodes of optic neuritis, and is not recommended for treating the disorder.

Prognosis

The vision loss associated with optic neuritis is usually temporary. Spontaneous remission occurs in two to eight weeks. Sixty-five to eighty percent of patients can expect 20/30 or better vision after recovery. Long-term prognosis depends on the underlying cause of the condition. If a viral infection has triggered the episode, it frequently resolves itself with no after effects. If optic neuritis is associated with multiple sclerosis, future episodes are not uncommon. Thirty-three percent of optic neuritis cases recur within five years. Each recurrence results in less recovery and worsening vision. There is a strong association between optic neuritis and MS. In those without multiple sclerosis, half who experience an episode of vision loss related to optic neuritis will develop the disease within 15 years.

Prevention

Regular annual eye exams are critical to maintaining healthy vision. Early treatment of vision problems can prevent permanent optic nerve damage (atrophy).

Oral contraceptives

Definition

Oral contraceptives are medicines taken by mouth to help prevent **pregnancy**. They are also known as "the Pill," OCs, or birth-control pills.

Purpose

Oral contraceptives, birth-control pills, contain artificially made forms of two hormones produced naturally in the body. These hormones, estrogen and progestin, regulate a woman's menstrual cycle. When taken in the proper amounts, following a specific schedule, oral contraceptives are very effective in preventing pregnancy. Studies show that fewer than one of every 100 women who use oral contraceptives correctly becomes pregnant during the first year of use.

These pills have several effects that help prevent pregnancy. For pregnancy to occur, an egg must become mature inside a woman's ovary, be released, and travel to the fallopian tube. A male sperm must also reach the fallopian tube, where it fertilizes the egg. Then the fertilized egg must travel to the woman's uterus (womb), where it lodges in the uterus' lining and develops into a fetus. The main way that oral contraceptives prevent pregnancy is by keeping an egg from ripening fully. Eggs that do not ripen fully cannot be fertilized. In addition, birth-control pills thicken mucus in the woman's cervix, through which the sperm has to swim. This makes it more difficult for the sperm to reach the egg. Oral contraceptives also thin the uterine lining so that a fertilized egg cannot lodge there and develop.

Birth-control pills may cause good or bad side effects. For example, a woman's menstrual periods are regular and usually lighter when she is taking

WWW.BOOKBAZ.IR

A package of birth-control pills, an oral contraceptive. *(Lew Robertson/Brand X Pictures/Getty Images.)*

oral contraceptives, and the pills may reduce the risk of **ovarian cysts**, breast lumps, **pelvic inflammatory disease**, and other medical problems. However, taking birth-control pills increases the risk of **heart attack**, **stroke**, and **blood clots** in women with a family history of **heart disease**. Serious side effects such as these are more likely in women over 35 years of age who smoke cigarettes and in those with specific health problems such as high blood pressure, diabetes, or a history of breast or uterine cancer. A woman who wants to use oral contraceptives should ask her physician for the latest information on the risks and benefits of all types of birth control and should consider her age, health, and medical history when deciding what to use.

Precautions

No form of birth control (except not having sex) is 100% effective. However, oral contraceptives can be highly effective when used properly. Discuss the options with a healthcare professional.

Oral contraceptives do not protect against **AIDS** or other sexually transmitted diseases. For protection against such diseases, use a latex condom.

Oral contraceptives are not effective immediately after a woman begins taking them. Physicians recommend using other forms of birth control for the first 1–3 weeks. Follow the instructions of the physician who prescribed the medicine.

Smoking cigarettes while taking oral contraceptives greatly increases the risk of serious side effects. *Women who take oral contraceptives should not smoke cigarettes.*

Seeing a physician regularly while taking this medicine is very important. The physician will note unwanted side effects. Follow his or her advice on how often you should be seen.

Anyone taking oral contraceptives should be sure to tell the healthcare professional in charge before having any surgical or dental procedures, laboratory tests, or emergency treatment.

This medicine may increase sensitivity to sunlight. Women using oral contraceptives should avoid too much sun exposure and should not use **tanning** beds, tanning booths, or sunlamps until they know how the medicine affects them. Some women taking oral contraceptives may get brown splotches on exposed areas of their skin. These usually go away over time after the women stop taking birth-control pills.

When possible, birth-control pills ought to be stopped for one month prior to, and not started again until two weeks after, major surgery involving prolonged immobility and/or an increased risk of blood clots.

Oral contraceptives may cause the gums to become tender and swollen, or to bleed. Careful brushing and flossing, gum massage, and regular cleaning may help prevent this problem. Check with a physician or dentist if gum problems develop.

Women who have certain medical conditions or who are taking certain other medicines may have problems if they take oral contraceptives. Before taking these drugs, be sure to let the physician know about any of these conditions:

ALLERGIES. Anyone who has had unusual reactions to estrogens or progestins in the past should let her physician know before taking oral contraceptives. The physician should also be told about any **allergies** to foods, dyes, preservatives, or other substances.

PREGNANCY. Women who become pregnant or think they may have become pregnant while taking birth-control pills should stop taking them immediately

and check with their physicians. Women who want to start taking oral contraceptives again after pregnancy should not refill their old prescriptions without checking with their physicians. The physician may need to change the prescription.

BREASTFEEDING. Women who are **breastfeeding** should check with their physicians before using oral contraceptives. The hormones in the pills may reduce the amount of breast milk and may pass to babies via milk. They may also cause **jaundice** and enlarged breasts in nursing babies whose mothers take the medicine.

OTHER MEDICAL CONDITIONS. Oral contraceptives may improve or worsen some medical conditions. The possibility that they may make a condition worse does not necessarily mean they cannot be used. In some cases, women may need only to be tested or followed more closely for medical problems while using oral contraceptives. Before using oral contraceptives, women with any of these medical problems should make sure their physicians are aware of their conditions:

- Female conditions such as menstrual problems, endometriosis, or fibroid tumors of the uterus. Birth-control pills usually make these problems better, but may sometimes make them worse or more difficult to diagnose.
- Heart or circulation problems; recent or past blood clots or stroke. Women who already have these problems may be at greater risk of developing blood clots or circulation problems if they use oral contraceptives. However, healthy women who do not smoke may lower their risk of circulation problems and heart disease by taking the pills.
- Breast cysts, lumps, or other non-cancerous breast problems. Oral contraceptives generally protect against these conditions, but physicians may recommend more frequent breast exams for women taking the pills.
- Breast cancer or other cancer (now or in the past, or family history). Oral contraceptives may make some existing cancers worse. Women with a family history of breast cancer may need more frequent screening for the disease if they decide to take birth-control pills.
- Migraine headaches. This condition may improve, but sometimes worsens with the use of birth-control pills.
- Diabetes. Blood sugar levels may increase slightly when oral contraceptives are used. Usually this increase is not enough to affect the amount of diabetes medicine needed. However, blood sugar will need to be monitored closely while taking oral contraceptives.
- Depression. This condition may worsen in women who already have it or may (rarely) occur again in women who were depressed in the past.
- Gallbladder disease, gallstones, high blood cholesterol, or chorea gravidarum (a nervous disorder). Oral contraceptives may make these conditions worse.
- Epilepsy, high blood pressure, heart or circulation problems. By increasing fluid build-up, oral contraceptives may make these conditions worse.

Description

Oral contraceptives (birth-control pills) come in a wide range of estrogen-progestin combinations. The pills in use today contain much lower doses of estrogen than those available in the past; these changes have reduced the likelihood of serious side effects. Some pills contain only progestin. These are prescribed mainly for women who need to avoid estrogens and may not be as effective in preventing pregnancy as the estrogen-progestin combinations.

These medicines come in tablet form, in containers designed to help women keep track of which tablet to take each day. The tablets are different colors, indicating amounts of hormones they contain. Some may contain no hormones at all. These are included simply to help women stay in the habit of taking a pill every day, as the hormone combination needs to be taken only on certain days of the menstrual cycle. Keeping the tablets in their original container and taking them exactly on schedule is very important. They will not be as effective if taken in the wrong order or if doses are missed.

Oral contraceptives are available only with a physician's prescription. Some commonly used brands are Demulen, Desogen, Loestrin, Lo/Ovral, Nordette, Ortho-Novum, Ortho-Tri-Cyclen, Estrostep, Ortho-cept, Alesse, Levlite and Ovcon.

The dose schedule depends on the type of oral contraceptive. The two basic schedules are a 21-day schedule and a 28-day schedule. On the 21-day schedule, take one tablet a day for 21 days, then skip 7 days and repeat the cycle. On the 28-day schedule, take one tablet a day for 28 days; then repeat the cycle. Be sure to carefully follow the instructions provided with the medicine. For additional information or explanations, check with the physician who prescribed the medicine or the pharmacist who filled the prescription.

Taking doses more than 24 hours apart may increase the chance of side effects or pregnancy. Try to take the medicine at the same time every day. Take care not to run out of pills. If possible, keep an extra

WWW.BOOKBAZ.IR

month's supply on hand and replace it every month with the most recently filled prescription.

Try not to miss a dose, as this increases the risk of pregnancy. If a dose is missed, follow the package directions or check with the physician who prescribed the medicine for instructions. It may be necessary to use another form of birth control for some time after missing a dose.

Taking this medicine with food or at bedtime will help prevent nausea, a side effect that sometimes occurs during the first few weeks. Nausea usually goes away as the body adjusts to the medicine.

Taking oral contraceptives may have several benefits outside of their ability to prevent pregnancy. Research indicates that with 10 to 12 years of oral contraceptive use, a woman's risk of **ovarian cancer** is reduced by up to 80%. There may also be an approximate 50% decrease in the rate of endometrial cancers in women. Another well-known, non-contraceptive benefit of taking oral contraceptives is improvement in **acne**. The combination oral contraceptive ethinyl estradiol/norgestimate has been approved by the U.S. Food and Drug Administration for the treatment of acne. Another positive effect of oral contraceptive use is improvement in abnormal uterine bleeding. Older women may also benefit from using oral contraceptives, because the pills can increase bone mass as women enter their menopausal years, when **osteoporosis** is a growing concern.

Oral contraceptives may be used on an emergency basis as a means of preventing pregnancy in women who have had unprotected intercourse. Plan B is available for this use, over the counter, in most drug stores.

Risks

Taking oral contraceptives with certain other drugs may affect the way the drugs work or may increase the chance of side effects.

Side effects

Serious side effects are rare in healthy women who do not smoke cigarettes. In women with certain health problems, however, oral contraceptives may cause problems such as **liver cancer**, non-cancerous liver tumors, blood clots, or stroke. Healthcare professionals can help women weigh the benefits of being protected against unwanted pregnancy against the risks of possible health problems.

The most common minor side effects include emotional lability (swings), nausea; **vomiting**; abdominal cramping or bloating; breast **pain**, tenderness or swelling; swollen ankles or feet; tiredness; and acne. These usually go away as the body adjusts to the drug, and do not need medical attention unless they persist or interfere with normal activities.

Other side effects should be brought to the attention of the physician who prescribed the medicine. Check with the physician as soon as possible if any of the following side effects occur:

- missed periods, longer periods, or bleeding or spotting between periods
- headaches
- vaginal infection, itching, or irritation
- increased blood pressure

Women who have any of the following symptoms should get emergency help right away. These symptoms may be signs of blood clots:

- sudden changes in vision, speech, breathing, or coordination
- severe or sudden headache
- coughing up blood
- sudden, severe, or continuing pain in the abdomen or stomach
- pain in the chest, groin, or leg (especially in the calf)
- weakness, numbness, or pain in an arm or leg

Oral contraceptives may continue to affect the menstrual cycle for some time after a woman stops taking them. Women who miss periods for several months after stopping this medicine should check with their physicians.

Other rare side effects may occur. Anyone who has unusual symptoms while taking oral contraceptives should get in touch with her physician.

Interactions

Oral contraceptives interact with a number of other medicines. When this happens, the effects of one or both of the drugs may change or the risk of side effects may be greater. Anyone who takes oral contraceptives should let the physician know all other medicines she is taking and should ask whether the possible interactions can interfere with drug therapy.

These drugs may make oral contraceptives less effective in preventing pregnancy. Anyone who takes these drugs should use an additional birth control method for the entire cycle in which the medicine is used:

- ampicillin
- penicillin V
- rifampin (Rifadin)
- tetracyclines

KEY TERMS

Cyst—An abnormal sac or enclosed cavity in the body, filled with liquid or partially solid material.

Endometriosis—A condition in which tissue, like that normally found in the lining of the uterus, is present outside the uterus. The condition often causes pain and bleeding.

Fallopian tube—One of a pair of slender tubes that extend from each ovary to the uterus. Eggs pass through the fallopian tubes to reach the uterus.

Fetus—A developing baby inside the womb.

Fibroid tumor—A noncancerous tumor formed of fibrous tissue.

Hormone—A substance that is produced in one part of the body, then travels through the bloodstream to another part of the body where it has its effect.

Jaundice—Yellowing of the eyes and skin due to the build up of a bile pigment (bilirubin) in the blood.

Migraine—A throbbing headache that usually affects only one side of the head. Nausea, vomiting, increased sensitivity to light, and other symptoms often accompany migraine.

Mucus—Thick fluid produced by the moist membranes that line many body cavities and structures.

Ovary—A reproductive organ in females that produces eggs and hormones.

Pelvic inflammatory disease—Inflammation of the female reproductive tract, caused by any of several microorganisms. Symptoms include severe abdominal pain, high fever, and vaginal discharge. Severe cases can result in sterility. Also called PID.

Uterus—A hollow organ in a female in which a fetus develops until birth.

- griseofulvin (Gris-PEG, Fulvicin)
- corticosteroids
- barbiturates
- carbamazepine (Tegretol)
- phenytoin (Dilantin)
- primidone (Mysoline)
- ritonavir (Norvir)
- modafinil (Provigil)
- oxcarbazepine (Trileptal)
- St John's wort

In addition, taking these medicines with oral contraceptives may increase the risk of side effects or interfere with the medicine's effects:

- theophylline—effects of this medicine may increase, along with the chance of unwanted side effects and possible toxicity
- cyclosporine—effects of this medicine may increase, along with the chance of unwanted side effects

The list above does not include every drug that may interact with oral contraceptives. Be sure to check with a physician or pharmacist before combining oral contraceptives with any other prescription or nonprescription (over-the-counter) medicine.

As with any medication, the benefits and risks should be discussed with a physician.

Oral hygiene

Definition

Oral hygiene is the practice of keeping the mouth clean and healthy by brushing and flossing to prevent **tooth decay** and gum disease.

Purpose

The purpose of oral hygiene is to prevent the build-up of plaque, the sticky film of bacteria and food that forms on the teeth. Plaque adheres to the crevices and fissures of the teeth and generates acids

WWW.BOOKBAZ.IR

that, when not removed on a regular basis, slowly eat away, or decay, the protective enamel surface of the teeth, causing holes (cavities) to form. Plaque also irritates gums and can lead to gum disease (**periodontal disease**) and tooth loss. Toothbrushing and flossing remove plaque from teeth, and antiseptic mouthwashes kill some of the bacteria that help form plaque. Fluoride—in toothpaste, drinking water, or dental treatments—also helps to protect teeth by binding with enamel to make it stronger. In addition to such daily oral care, regular visits to the dentist promote oral health. Preventative services that he or she can perform include fluoride treatments, sealant application, and scaling (scraping off the hardened plaque, called tartar). The dentist can also perform such diagnostic services as x-ray imaging and oral cancer screening as well as such treatment services as fillings, crowns, and bridges.

Precautions

Maintaining oral hygiene should be a lifelong habit. An infant's gums and, later, teeth should be kept clean by wiping them with a moist cloth or a soft toothbrush. However, only a very small amount (the size of a pea) of toothpaste containing fluoride should be used since too much fluoride may be toxic to infants.

An adult who has partial or full dentures should also maintain good oral hygiene. Bridges and dentures must be kept clean to prevent gum disease. Dentures should be relined and adjusted by a dentist as necessary to maintain proper fit so the gums do not become red, swollen, and tender.

Brushing and flossing should be performed thoroughly but not too vigorously. Rough mechanical action may irritate or damage sensitive oral tissues. Sore or bleeding gums may be experienced for the first few days after flossing is begun. However, bleeding continuing beyond one week should be brought to the attention of a dentist. As a general rule, any sore or abnormal condition that does not disappear after 10 days should be examined by a dentist.

Description

Brushing

Brushing should be performed with a toothbrush and a fluoride toothpaste at least twice a day and preferably after every meal and snack. Effective brushing must clean each outer tooth surface, inner tooth surface, and the flat chewing surfaces of the back teeth. To clean the outer and inner surfaces, the toothbrush should be held at a 45-degree angle against the gums and moved back and forth in short strokes (no more than one toothwidth distance). To clean the inside surfaces of the front teeth, the toothbrush should be held vertically and the bristles at the tip (called the toe of the brush) moved gently up and down against each tooth. To clean the chewing surfaces of the large back teeth, the brush should be held flat and moved back and forth. Finally, the tongue should also be brushed using a back-to-front sweeping motion to remove food particles and bacteria that may sour the breath.

Toothbrushes wear out and should be replaced every three months. Consumers should look for toothbrushes with soft, nylon, rounded bristles in a size and shape that allows them to reach all tooth surfaces easily.

Holding a toothbrush may be difficult for people with limited use of their hands. The toothbrush handle may be modified by inserting it into a rubber ball for easier gripping.

Flossing

Flossing once a day helps prevent gum disease by removing food particles and plaque at and below the gumline as well as between teeth. To begin, most of an 18-in (45-cm) strand of floss is wrapped around the third finger of one hand. A 1-in (2.5-cm) section is then grasped firmly between the thumb and forefinger of each hand. The floss is eased between two teeth and worked gently up and down several times with a rubbing motion. At the gumline, the floss is curved first around one tooth and then the other with gentle sliding into the space between the tooth and gum. After each tooth contact is cleaned, a fresh section of floss is unwrapped from one hand as the used section of floss is wrapped around the third finger of the opposite hand. Flossing proceeds between all teeth and behind the last teeth. Flossing should also be performed around the abutment (support) teeth of a bridge and under any artificial teeth using a device called a floss threader.

Dental floss comes in many varieties (waxed, unwaxed, flavored, tape) and may be chosen on personal preference. For people who have difficulty handling floss, floss holders and other types of interdental (between the teeth) cleaning aids, such as brushes and picks, are available.

Results

With proper brushing and flossing, oral hygiene may be maintained and oral health problems may be avoided. Older adults may no longer assume that they will lose all of their teeth in their lifetime. Regular oral

KEY TERMS

Calculus—A hardened yellow or brown mineral deposit from unremoved plaque; also called tartar.

Cavity—A hole or weak spot in the tooth surface caused by decay.

Gingivitis—Inflammation of the gums, seen as painless bleeding during brushing and flossing.

Interdental—Between the teeth.

Periodontal—Pertaining to the gums.

Periodontitis—A gum disease that destroys the structures supporting the teeth, including bone.

Plaque—A thin, sticky, colorless film of bacteria that forms on teeth.

Tartar—A hardened yellow or brown mineral deposit from unremoved plaque; also called calculus.

care preserves speech and eating functions, thus prolonging the quality of life.

Risks

Negative consequences arise from improper or infrequent brushing and flossing. The five major oral health problems are plaque, tartar, gingivitis, periodontitis, and tooth decay.

Plaque is a soft, sticky, colorless bacterial film that grows on the hard, rough surfaces of teeth. These bacteria use the sugar and starch from food particles in the mouth to produce acid. Left to accumulate, this acid destroys the outer enamel of the tooth, irritates the gums to the point of bleeding, and produces foul breath. Plaque starts forming again on teeth four to 12 hours after brushing, so brushing a minimum of twice a day is necessary for adequate oral hygiene.

When plaque is not regularly removed by brushing and flossing, it hardens into a yellow or brown mineral deposit called tartar or calculus. This formation is crusty and provides additional rough surfaces for the growth of plaque. When tartar forms below the gumline, it can lead to periodontal (gum) disease.

Gingivitis is an early form of periodontal disease, characterized by inflammation of the gums with painless bleeding during brushing and flossing. This common condition is reversible with proper dental care but if left untreated, it will progress into a more serious periodontal disease, periodontitis.

Periodontitis is a gum disease that destroys the structures supporting the teeth, including bone. Without support, the teeth will loosen and may fall out or have to be removed. To diagnose periodontitis, a dentist looks for gums that are red, swollen, bleeding, and shrinking away from the teeth, leaving widening spaces between teeth and exposed root surfaces vulnerable to decay.

Tooth decay, also called dental caries or cavities, is a common dental problem that results when the acid produced by plaque bacteria destroys the outer surface of a tooth. A dentist will remove the decay and fill the cavity with an appropriate dental material to restore and protect the tooth; left untreated, the decay will expand, destroying the entire tooth and causing significant **pain**.

Orbital and periorbital cellulitis

Definition

Cellulitis is a confined or widespread inflammation of any of the body's connective tissue, along with the dermal and subcutaneous layers of the skin. When there is inflammation of the tissue and skin surrounding the eye, then it is called ocular cellulitis, which can be classified more narrowly as orbital cellulitis and periorbital cellulitis. Specifically, orbital cellulitis is inflammation of the eye structures within the bony cavity of the front of the head (face). It is described as swelling around the eye but not within the eyeball itself—the eyeball usually appears normal. Periorbital cellulitis, also known as preseptal cellulitis, is an inflammation of the area from the skin of the eyelid to the bony portion that encircles the eye.

Description

Inside the eyelid is a septum (palpebral ligament), a membranous sheet that divides the eyelid into outer

WWW.BOOKBAZ.IR

and inner areas. It acts as the frontal boundary of the orbit (cavity of the skull where the eye and its appendages are located), extending from the orbital rim to the eyelid. The septum helps prevent the spread of infection to the eye socket.

Orbital and periorbital cellulitis, together, refers to inflammation and infection of the skin and tissue that surrounds the eye. However, when inflammation reaches inside the septum, then it is called orbital cellulitis, whereas inflammation outside the septum is termed periorbital cellulitis. Both are usually caused by bacterial infection but can also be caused by direct **trauma** to the eye or from an infection that originates in the sinuses.

Orbital and periorbital cellulitis are more common in children than in adults. Periorbital cellulitis, which accounts for 85–90% of all ocular cellulitis, usually occurs in children under the age of five years. Responsible for the remaining 10–15% of these infections, orbital cellulitis is most common in children over the age of five years.

These conditions usually begin with swelling or inflammation of one eye. Infection spreads rapidly and can cause serious problems that affect the eye or the whole body. Both of the conditions are serious and require immediate medical attention to prevent complications such as **brain abscess**, **meningitis**, or vision loss.

Demographics

Before the widespread use of **antibiotics**, patients with orbital cellulitis had a mortality rate of 17%. Those patients that survived had a one in five chance (20%) of becoming blind in the affected eye. However, the use of antibiotics has reduced these statistics significantly. Despite prompt diagnosis and prompt use of antibiotics, blindness still occurs in up to 11% of cases.

Orbital cellulitis occurs twice as often in male children as it does in female children. Children are more likely to be hospitalized with the condition when they are from seven to 12 years of age. In adults, no difference exists due to gender except for those cases that involve methicillin-resistant *Staphylococcus aureus* (MRSA). In such cases, females are four times more likely to acquire orbital cellulitis than are males. Unfortunately, orbital cellulitis due to MRSA can lead to blindness despite prompt antibiotic treatment.

Causes and symptoms

Orbital and periorbital forms of cellulitis are usually caused by infection of the sinuses near the nose. Insect bites or injuries that break the skin cause about one-third of these cellulitis infections. Orbital and periorbital cellulitis may also occur in people with a history of dental infections.

The blood of about 33 of every 100 patients with orbital or periorbital cellulitis contains bacteria known to cause the following:

- acute ear infections
- inflammation of the epiglottis
- meningitis (inflammation of the membranes that enclose and protect the brain)
- pneumonia
- sinus infection

The most common bacteria that cause orbital or periorbital cellulitis are *Staphylococcus aureus*, *Streptococcur pyogenes*, and *Haemophilus influenzae*.

People with periorbital cellulitis have swollen, painful upper and lower eyelids and redness, **fever**, **pain**, and general discomfort of the eye. About one child in five has a runny nose, and 20% have **conjunctivitis**. Conjunctivitis, also called pinkeye, is an inflammation of the mucous membrane that lines the eyelid and covers the front white part of the eye. It can be caused by allergy, irritation, or bacterial or viral infection.

In addition to swollen eyelids, other symptoms of orbital cellulitis include:

- bulging or displacement of the eyeball (proptosis)
- chemosis (swelling of the mucous membrane of the eyeball and eyelid as a result of infection, injury, or systemic disorders like anemia or kidney disease)
- diminished ability to see clearly
- eye pain and general discomfort of the eye
- fever
- paralysis of nerves that control eye movements (ophthalmoplegia)

Diagnosis

An eye doctor may use special instruments to open a swollen lid in order to examine the position of the eyeball, evaluate eye movement, and test the patient's vision.

If the source of infection is not apparent, the position of the eyeball may suggest its location. Computed tomography (CT) scans can indicate which sinuses and bones are involved or whether abscesses have developed. X-ray scans may also be used to produce images of the tissues and bones around the eye. **Magnetic resonance imaging** (MRI) scans may used in the diagnosis of such infections. Blood tests,

KEY TERMS

Epiglottis—The cartilage flap that covers the opening of the windpipe during swallowing.

Meningitis—An infection of the outside of the brain and the spinal cord.

Methicillin-resistant *Staphylococcus aureus* (MRSA)—A bacteria that is resistant to many antibiotics.

Orbit—The cavity of the skull in which the eye and its appendages are located.

Orbital septum—A membrane-like sheet that functions as the anterior boundary of the orbit within the eye.

such as **complete blood count** (CBC), are also beneficial for further diagnosis, as are cultures taken of the drainage from affected eyes.

Treatment

Individuals with orbital or periorbital cellulitis should be hospitalized without delay; prompt treatment prevents complications and makes the healing process that much quicker. Oral antibiotics are used to stop the spread of infection and prevent damage to the optic nerve, which transmits visual images to the brain. Intravenous (IV) antibiotics may also be used when the seriousness of the condition is apparent. Surgery to allow drainage of the sinuses or eye sockets or to remove abscesses of the eye is sometimes also needed. An ophthalmologist or otolaryngologist should perform these surgical procedures.

Symptoms of optic-nerve damage or infection that has spread to sinus cavities close to the brain include:

- impaired response of the pupil to light and other stimulus
- loss of visual acuity
- papilledema (swelling of the optic disk—where the optic nerve enters the eye)
- very limited ability to move the eye

Prognosis

If diagnosed promptly and treated with antibiotics, most orbital and periorbital cellulitis can be cured. These conditions are serious and need prompt treatment. Infections that spread beyond the eye socket can cause the following:

- abscesses in the brain or in the protective membranes that enclose it
- bacterial meningitis
- blood clots
- vision loss

Prevention

It is difficult to prevent orbital and periorbital cellulitis. However, proper care to avoid conditions that can lead to orbital and periorbital cellulitis, such as **sinusitis** and dental disease, can help reduce the risks of getting them.

REVISED BY WILLIAM A. ATKINS, BB, BS, MBA

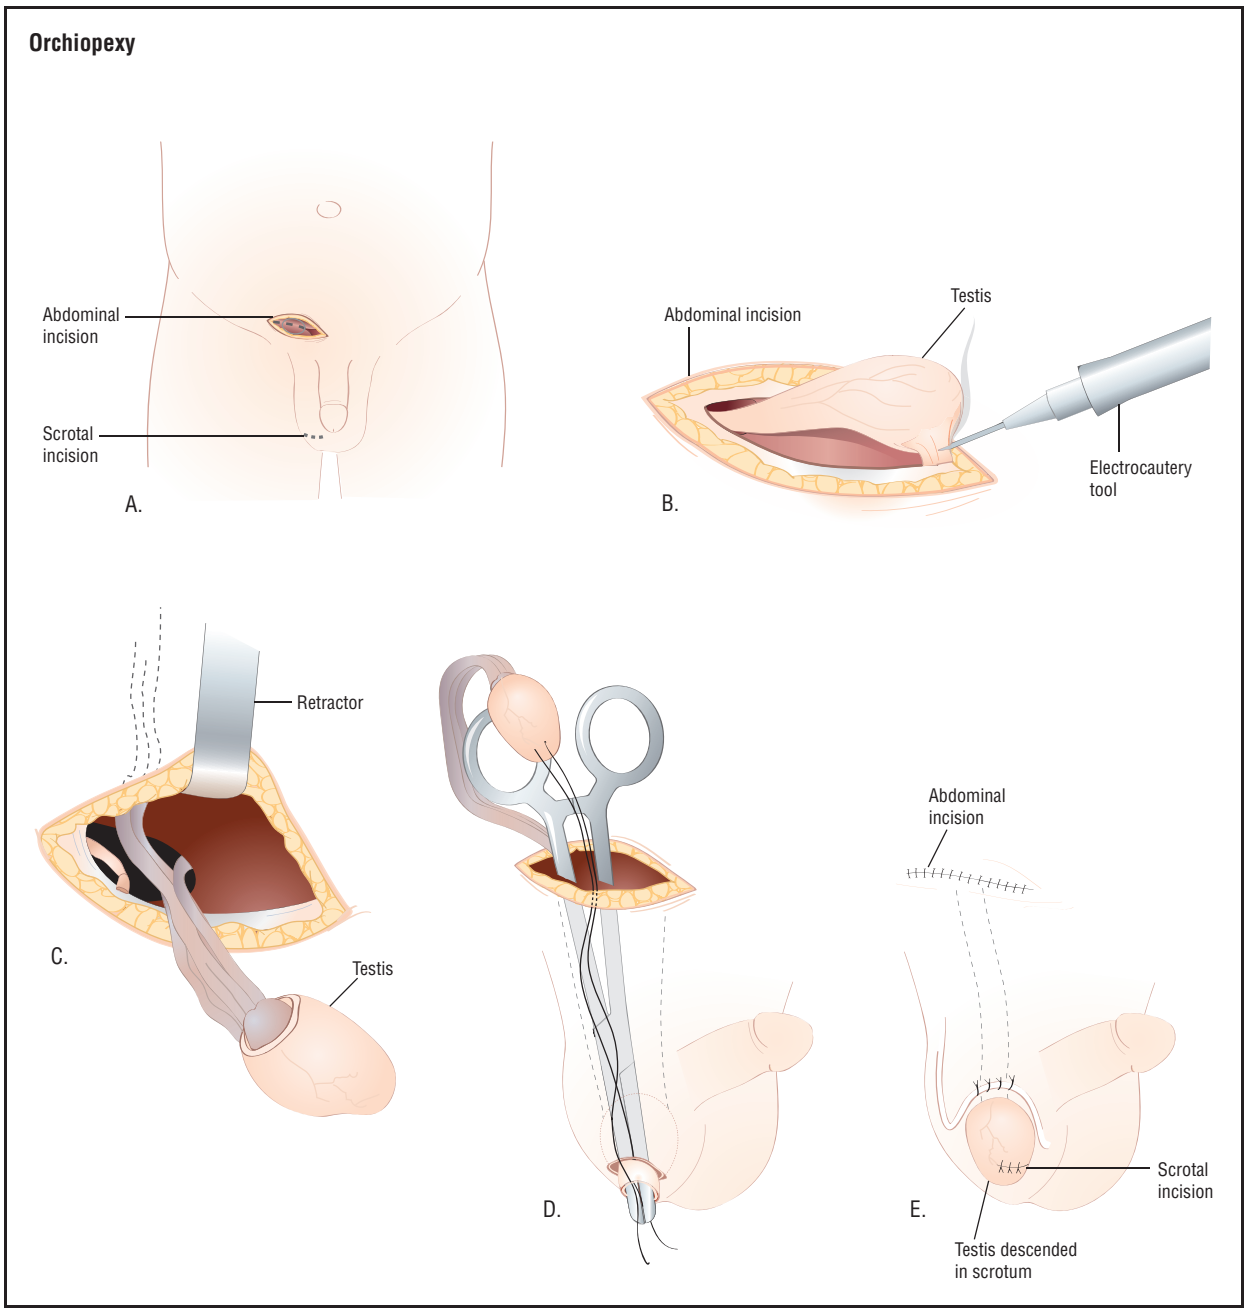
Orchiectomy *see* **Testicular surgery**

Orchiopexy

Definition

Orchiopexy is a procedure in which a surgeon fastens an undescended testicle inside the scrotum, usually with absorbable sutures. It is done most often in male infants or very young children to correct cryptorchidism, which is the medical term for undescended testicles. Orchiopexy is also occasionally performed in adolescents or adults, and

WWW.BOOKBAZ.IR



An orchiopexy is used to repair an undescended testicle in childhood. An incision is made into the abdomen, the site of the undescended testicle, and another is made in the scrotum (A). The testis is detached from surrounding tissues (B) and pulled out of the abdominal incision attached to the spermatic cord (C). The testis is then pulled down into the scrotum (D) and stitched into place (E). *(Illustration by GGS Information Services. Copyright © Cengage Learning®.)*

may involve one or both testicles. In adults, orchiopexy is most often done to treat **testicular torsion**, which is a urologic emergency resulting from the testicle's twisting around the spermatic cord and losing its blood supply.

Other names for orchiopexy include orchidopexy, inguinal orchiopexy, repair of undescended testicle, cryptorchidism repair, and testicular torsion repair.

Purpose

To understand the reasons for performing an orchiopexy in children, it is helpful to have an outline of the normal pattern of development of the testes in a male infant. The gubernaculum is an embryonic cord-like ligament that attaches the testes within the inguinal (groin) region of a male fetus up through the

KEY TERMS

Cremasteric reflex—A reflex in which the cremaster muscle, which covers the testes and the spermatic cord, pulls the testicles back into the scrotum. It is important for a doctor to distinguish between an undescended testicle and a hyperactive cremasteric reflex in small children.

Cryptorchidism—A developmental disorder in which one or both testes fail to descend from the abdomen into the scrotum before birth. It is the most common structural abnormality in the male genital tract.

Ectopic—Located in an abnormal site or tissue. An ectopic testicle is one that is located in an unusual position outside its normal line of descent into the scrotum.

Gonadotropins—Hormones that stimulate the activity of the ovaries in females and testes in males.

Hernia—The protrusion of a loop or piece of tissue through an incision or abnormal opening in other tissues.

Inguinal—Referring to the groin area.

Laparoscope—An instrument that allows a surgeon to look inside the abdominal cavity.

Nonpalpable—Unable to be detected through the sense of touch. A nonpalpable testicle is one that is located in the abdomen or other site where the doctor cannot feel it by pressing gently on the child's body.

Orchiectomy—Surgical removal of one or both testicles in a male; also called an orchidectomy.

Perineum—The area between the scrotum and the anus.

Peritoneum—The smooth, colorless membrane that lines the inner surface of the abdomen.

Prune belly syndrome (PBS)—A genetic disorder associated with abnormalities of human chromosomes 18 and 21. Male infants with PBS often have cryptorchidism along with other defects of the genitals and urinary tract. PBS is also known as triad syndrome and Eagle-Barrett syndrome.

Scrotum—The pouch of skin on the outside of the male body that holds the testes.

Spermatic cord—A tube-like structure that extends from the testicle to the groin area. It contains blood vessels, nerves, and a duct to carry spermatic fluid.

Testicular torsion—Twisting of the testicle around the spermatic cord, cutting off the blood supply to the testicle. It is considered a urologic emergency.

Testis (plural, testes)—The medical term for a testicle.

Urology—The branch of medicine that deals with disorders of the urinary tract in both males and females, and with the genital organs in males.

seventh month of **pregnancy**. Between the 28th and the 35th week of pregnancy, the gubernaculum migrates into the scrotum and creates space for the testes to descend. In normal development, the testes have followed the gubernaculum downward into the scrotum by the time the baby is born. The normal pattern may be interrupted by several possible factors, including inadequate androgen (male sex hormone) secretion, structural abnormalities in the boy's genitals, and defective nerves in the genital region.

Orchiopexy is performed in children for several reasons:

- To minimize the risk of infertility. Adult males with cryptorchidism typically have lower sperm counts and produce sperm of poorer quality than men with normal testicles. The risk of infertility rises with increasing age at the time of orchiopexy and whether both testicles are affected. Men with one undescended testicle have a 40% chance of being infertile; this figure rises to 70% in men with bilateral cryptorchidism.
- To lower the risk of testicular cancer. The incidence of malignant tumors in undescended testes has been estimated to be 48 times the incidence in normal testes. Men with cryptorchidism have a 10% chance of eventually developing testicular cancer.
- To lower the risk of traumatic injury to the testicle. Undescended testicles that remain in the patient's groin area are vulnerable to sports injuries and pressure from car seat belts.
- To prevent the development of an inguinal hernia. An inguinal hernia is a disorder that occurs when a portion of the contents of the abdomen pushes through an abnormal opening in the abdominal wall. It is likely to occur in a male infant with cryptorchidism because a sac known as the processus vaginalis, which connects the scrotum and the abdominal cavity, remains open after birth. In normal development, the processus vaginalis closes shortly after the testes descend into the scrotum. If the sac remains open, a section of the child's intestine can extend into the sac.

WWW.BOOKBAZ.IR

It may become trapped (incarcerated) in the sac, forming what is called a strangulated hernia. The portion of the intestine that is trapped in the sac may die, which is a medical emergency.

- To prevent testicular torsion in adolescence.
- To maintain the appearance of a normal scrotum. Orchiopexy is considered a necessary procedure for psychological reasons, as boys with only one visible testicle are frequently subjected to teasing and ridicule after they start school.

The primary reason for performing an orchiopexy in an adolescent or adult male is treatment of testicular torsion, rather than cryptorchidism. Testicles that have not descended by the time a boy reaches **puberty** are usually removed by a complete orchiectomy.

Demographics

Cryptorchidism

Cryptorchidism is the most common abnormality of the male genital tract, affecting 3–5% of full-term male infants and 30–32% of premature male infants. In most cases, the condition resolves during the first few months after delivery; only 0.8% of infants over three months of age still have undescended testicles. Because of the potentially serious consequences of cryptorchidism, however, doctors do not advise watchful waiting once the child is over six months old. Undescended testicles rarely come down into the scrotum of their own accord after that age.

Cryptorchidism is a frequent occurrence in prune belly syndrome (PBS) and a few other genetic disorders characterized by structural abnormalities of the genitourinary tract.

No variation in the incidence of cryptorchidism among different racial and ethnic groups has been reported.

Testicular torsion

Most American males suffering from testicular torsion are below age 30, with the majority between the ages of 12 and 18. The peak ages for an acute episode of testicular torsion are the first year of life and age 14. Testicular torsion occurs on the left side of the body slightly more often than on the right side, about 52% versus 48% of cases.

Description

A pediatric surgeon or pediatric urologist is the specialist most likely to perform an orchiopexy in an infant or small child. In an adult patient, the procedure is usually performed by a urologist after referral from the patient's primary physician or the emergency care physician.

An orchiopexy can be performed in the surgical unit of a children's hospital or an ambulatory surgical center. Most orchiopexies in adults are performed as outpatient procedures.

Cryptorchidism

Some orchiopexies in children are relatively simple procedures; however, others are complicated by the location of the undescended testicle. In general, an orchiopexy for an undescended testicle that lies in front of the scrotum or just above it is a less complicated operation than one done to treat a nonpalpable testicle. The procedure is usually done under general **anesthesia**.

If the undescended testis is in the groin area, the surgeon will make a small incision in the groin and a second small incision in the scrotum. The testis is moved downward from the groin without complete separation from the gubernaculum. It is then placed inside a small pouch created by the surgeon between the skin of the scrotum and a layer of muscle in the scrotum called the dartos muscle. The testicle is held in place with sutures that are eventually absorbed by the body.

The Fowler-Stephens technique is often used when the undescended testicle is located high above the scrotum or in the abdomen. It may be done in two stages scheduled several months apart. In the first stage, the surgeon moves the testicle downward and attaches it temporarily to the inside of the thigh. In the second stage, the testicle is transferred into the scrotum itself and sutured into place.

A third type of orchiopexy is called testicular autotransplantation. The surgeon removes the undescended testicle completely from its present location and reimplants it in the scrotum by reattaching its surrounding tissues and blood vessels to nearby blood vessels. This technique minimizes the risk of an inadequate blood supply to the reimplanted testicle.

Testicular torsion

An orchiopexy done to treat testicular torsion is usually done under general or epidural anesthesia. The surgeon makes an incision in the patient's scrotum and untwists the spermatic cord. The affected testicle is inspected for signs of necrosis, or tissue death. If too much tissue has died due to loss of blood supply, the surgeon will remove the entire testicle. If the tissue appears to be healthy, the surgeon sutures the testicle to the wall of the scrotum and then closes the incision. In

most cases, the surgeon will also attach the unaffected testicle to the scrotal wall as a preventive measure.

Diagnosis

Cryptorchidism

The diagnosis of cryptorchidism is usually made when a pediatrician examines the newborn baby, although the condition can occur at any time before the boy reaches puberty. The first stage in diagnosis is an external **physical examination** of the child's genitals. If either testicle does not appear to be in the scrotum, the doctor will palpate, or touch, the groin area and abdomen to determine whether a testicle can be felt in any of those locations. If the testicle can be felt, the doctor will decide on the basis of its location whether it is an undescended testicle, a so-called ectopic testicle, or a retractile testicle. An ectopic testicle is one that has developed in a location outside the normal path of development in the inguinal canal. Ectopic testicles are most often discovered along the inner part of the thigh near the groin, at the base of the penis, or below the scrotum in the perineum (the area between the scrotum and the rectum). A retractile testicle is one that is readily pulled back out of the scrotum by an overly sensitive reflex called the cremasteric reflex; it is not a genuinely undescended testicle. It is important for the doctor to distinguish a retractile testicle from genuine cryptorchidism because retractile testicles do not need surgical treatment. At this point in the diagnostic workup, a general pediatrician will often consult a specialist in pediatric urology.

In about 20% of male infants with cryptorchidism, the missing testicle cannot be felt at all. It is known as a nonpalpable testicle. The child may be given a hormone challenge test to help determine whether the testicle is located in the abdomen or whether it has failed to develop fully. If the testosterone level in the blood rises in response to the test, the doctor knows that there is a testis present somewhere in the child's body. In other cases, the testis has atrophied, or shriveled up due to an inadequate blood supply before birth. If neither testicle can be felt, the child should be examined further for evidence of intersexuality. The doctor may order an **ultrasound** to check for the presence of a uterus, particularly if the child's external genitals are ambiguous in appearance.

Surgery is the next step in searching for a nonpalpable testicle. The surgeon may perform either an open inguinal procedure or a laparoscopic approach. In an open inguinal exploration, the surgeon makes an incision in the child's groin; if nothing is found, the incision may be extended into the lower abdomen. In a laparoscopic approach, the surgeon uses an instrument that looks like a small telescope with a light attached in order to see inside the groin or the abdominal cavity through a much smaller incision. If the surgeon is able to find the testicle, he or she may then proceed directly to perform an orchiopexy.

Testicular torsion

Testicular torsion is usually diagnosed in the emergency room. The doctor will usually suspect testicular torsion on the basis of sudden onset of severe **pain** on one side of the scrotum; it is unusual for pain to develop gradually in this disorder. The patient's history often indicates recent hard physical work, vigorous **exercise**, or **trauma** to the genital area; however, testicular torsion can also occur without any apparent reason. Other symptoms may include swelling of the scrotum, blood in the semen, **nausea and vomiting**, pain in the abdomen, and **fever**. A few patients feel the need to urinate frequently. When the doctor examines the patient's scrotum, the affected testicle is usually enlarged and is painful when the doctor touches it. It usually lies higher in the scrotum than the unaffected testicle and may be lying in a horizontal position.

Since testicular torsion is a medical emergency, most doctors will not risk permanent damage to the testicle by taking the time to perform imaging studies. If the diagnosis is unclear, however, the doctor may order a radionuclide scan or a color Doppler ultrasound to determine whether the blood flow to the testicle has been cut off. The patient will be given a mild pain medication and referred to a urologist for surgery as soon as possible.

Aftercare

Cryptorchidism

Aftercare in children depends partly on the complexity of the procedure. If the child has an uncomplicated orchiopexy, he can usually go home the same day. If the surgeon had to make an incision in the abdomen to find a nonpalpable testicle before performing the orchiopexy, the child may remain in the hospital for two to three days. The doctor will usually prescribe a pain medication for the first few days after the procedure.

After the child returns home, he should not bathe until the day after surgery. In addition, he should not ride a bicycle, climb trees, or do anything else that requires straddling for two to three weeks. An older boy should avoid sports or rough games that might result in injury to the genitals until he has a postsurgical checkup.

WWW.BOOKBAZ.IR

Most surgeons will schedule the child for a checkup one or two weeks after the orchiopexy, with a second checkup three months later.

Testicular torsion

Aftercare is similar to that for orchiopexy in a child. The area around the incision should be washed very gently the next day and a clean dressing applied. Medication will be prescribed for postoperative pain. The patient is advised to rest at home for several days after surgery, to remain in bed as much as possible, to drink extra fluids, and to elevate the scrotum on a small pillow to ease the discomfort. Vigorous physical and sexual activity should be avoided until the pain and swelling go away.

Results

In a normal orchiopexy, the testicle remains in the scrotum without reascending. If the procedure has been successful, there is no damage to the blood vessels supplying the testicle, no loss of fertility, and no recurrence of torsion.

Morbidity and mortality rates

CRYPTORCHIDISM. Orchiopexy is most likely to be successful in children when the undescended testicle is relatively close to the scrotum. The rate of failure for orchiopexy performed as a treatment for cryptorchidism is 8% if the testicle lies just above the scrotum; 10–20% if the testicle is located in the inguinal canal; and 25% if the testicle lies within the abdomen.

TESTICULAR TORSION. The mortality rate for orchiopexy in adults is very low because almost all patients are young males in good health. The procedure has a 99% rate of success in saving the testicle when the diagnosis is made promptly and treated within six hours. After 12 hours, however, the rate of success in saving the testicle drops to 2%. The average rate of testicular atrophy following orchiopexy for testicular torsion is about 27%.

Risks

Cryptorchidism

The risks of orchiopexy in treating cryptorchidism include:

- infection of the incision
- bleeding
- damage to the blood vessels and other structures in the spermatic cord, leading to eventual loss of the testicle
- failure of the testicle to remain in the scrotum (This problem can be repaired by a second operation.)
- difficulty urinating for a few days after surgery

Testicular torsion

The risks of orchiopexy as a treatment for testicular torsion include:

- infection of the incision
- bleeding
- loss of blood circulation in the testicle leading to loss of the testicle
- reaction to anesthesia

Alternatives

Cryptorchidism

Hormonal therapy using gonadotropins to stimulate the production of more testosterone is effective in some children in causing the testes to descend into the scrotum without surgery. This approach, however, is usually successful only with **undescended testes** that are already close to the scrotum; its rate of success ranges from 10–50%. Undescended testes that are located higher almost never respond to hormonal therapy. In addition, treatment with hormones has several undesirable side effects, including aggressive behavior.

Some surgeons will, however, prescribe hormonal treatment before an orchiopexy in order to increase the size of the undescended testis and make it easier to identify during surgery.

Testicular torsion

Pain caused by testicular torsion can be relieved temporarily by manual detorsion. To perform this maneuver, the doctor stands at the patient's feet and gently rotates the affected testicle toward the outside of the patient's body in a sideways direction. Manual detorsion is effective in relieving pain in 30–70% of patients; however, it is not considered an alternative to orchiopexy in preventing a recurrence of the torsion or loss of the testicle.

Orchitis

Definition

Orchitis is an inflammation of the testis, accompanied by swelling, **pain**, **fever**, and a sensation of heaviness in the affected area.

Description

Viral **mumps** is the most common cause of orchitis. Bacterial infections associated with the disorder are **tuberculosis**, **syphilis**, **gonorrhea**, and chlamydia. A mechanical injury to the groin area may also cause orchitis. Fifteen to twenty-five % of males past the age of **puberty** with mumps develop orchitis. Epididymo-orchitis (inflammation of both testes and part of the spermatic duct) is the most common bacterial type of orchitis. This form of the condition occurs most often in sexually active males 15 years and older, and in men over 45 with enlarged prostates.

KEY TERMS

Atrophy—A wasting away or withering.
Epididymo-orchitis—Inflammation of both the testes and a part of the spermatic duct system.
Unilateral—Affecting only one side.

Causes and symptoms

The people most susceptible to orchitis are those with inadequate mumps inoculation and, in the case of sexually transmitted orchitis, those who practice unsafe sex or have a history of sexually transmitted disease. Inadequate protection of the groin area during contact sports or other potentially harmful physical activities may result in injury leading to orchitis. Symptoms of orchitis include swelling of one or both testicles, tenderness in the groin area, fever, **headache**, and nausea. Symptoms may also include bloody discharge from the penis, and pain during urination, intercourse, or ejaculation.

Diagnosis

In most cases, Orchitis can be diagnosed by an urologist, general practitioner, or emergency room physician. Diagnosis is usually based on the results of a **physical examination** and patient history. Other testing may include a **urinalysis** and **urine culture**, screening for chlamydia and gonorrhea, **ultrasound** imaging, or blood tests.

Treatment

Elevation and support of the scrotum, and the application of cold packs to the groin area give some relief from the pain of orchitis. Medication for pain such as codeine and meperidine may be given. Only the symptoms of viral mumps orchitis are treated. **Antibiotics** are used to alleviate orchitis that is bacterial in origin. Sexually transmitted orchitis (especially when resultant from chlamydia or gonorrhea) is often treated with the antibiotic Ceftriaxone in conjunction with azithromycin or doxycycline.

Alternatives

For relief from swelling, the drinking of dandelion tea is recommended in **traditional Chinese medicine**

WWW.BOOKBAZ.IR

(TCM). Another traditional Chinese treatment for swelling is the application of a poultice of ground dandelion and aloe to the affected area. Homeopathic remedies to reduce swelling include apis mel, belladonna, and pulsatilla. Consult a homeopathic physician before taking or administering these remedies to ensure safe and correct dosage.

Prognosis

Orchitis is usually unilateral and lasts between one and two weeks. Atrophy of the scrotum occurs in 60% of orchitis cases. However, hormonal function is not affected and resulting sterility is rare from mumps.

Prevention

Keeping mumps inoculations current and diligently practicing **safe sex** are the best ways to prevent orchitis from occurring. For males involved in contact sports or other potentially harmful physical activities, the wearing of a protective cup over the genitals will help guard against mechanical injuries that could lead to orchitis.

Organ donation

Definition

Organ donation is the giving of a healthy body part from either a living or dead individual to another person.

Purpose

The purpose of organ donation is to improve and prolong the life of an ill or impaired individual.

Demographics

In the United States there is a mismatch between the number of people needing donated organs and the number of donors. At the end of December 2014, according to the United Network for Organ Sharing (UNOS), about 124,000 people were awaiting donor organs. Of those, about 85,000 needed a kidney donation and about 16,000 needed a liver donation. This compares to 1,892 deceased donors and 1,548 living donors who provided organs for donation in the first three months of 2010. Deceased donors often provided more than one organ for donation and accounted for 5,162 transplantations during that three month period.

Organ donation

Transplants performed[1]	
Total	14,140
Deceased donor	10,951
Living donor	3,189
Donors recovered[1]	
Total	7,136
Deceased donor	3,947
Living donor	3,189

[1]Data reflects number of transplants and donors from January 2010 to June 2010.

SOURCE: U.S. Department of Health and Human Services, Organ Procurement and Transplantation Network. Available online at: http://optn.transplant.hrsa.gov/data/default.asp (accessed September 23, 2010).

(Table by PreMediaGlobal. © Cengage Learning®.)

There is a special need for donors from minority ethnic groups. For example, about 12% of African Americans become organ donors but about 23% of individuals on the waiting list for a donated kidney are African American because of higher rates of **kidney disease** in the African American community. Although it is possible to make a match between people of different ethnic or racial groups, the likelihood of an appropriate genetic match (to prevent organ rejection) is much higher within ethnic groups.

Internationally, the rate of organ donation varies with religious and cultural norms and the level of sophistication of medical care. Many countries, such as the United States, are opt-in donation countries. This means that an individual must positively state his or her desire to donate body parts after death. A few countries have an opt-out donor system where individuals must state before death that they *do not* want to donate organs when they die. In all cases, individuals can specify which organs they wish to donate.

Description

Organ donation involves the matching of a person willing to give a healthy body part to an ill person who

needs that part. There are two types of organ donation: living donation and donation after death (cadaver donation). In the United States and in many other countries, the costs of the donation to both donor and recipient are paid by health insurance. In the United States, it is illegal to buy an organ or receive money for a donated organ. Both citizens and non-citizens can donate and receive body parts.

All organ donations in the United States are regulated by UNOS. A person approved for an organ donation is registered with UNOS and placed on their waiting list. UNOS has organ transplant specialists who run a national computer network that connects all the transplant centers and organ-donation organizations. Patients are grouped in terms of priority based on how long they can live without a transplant. The list is national and independent of the medical transplant center where the surgery will take place.

When a donor organ becomes available, information about the donor organ is entered into the UNOS computer and compared to information about patients on the waiting list. The computer program produces a list of patients ranked according to blood type and how urgently they need the organ. Because some organs (e.g., the heart) must be transplanted as quickly as possible, a list of local patients may be checked first for a good match. After that, a regional list and then a national list are checked. The patient's transplant team and transplant specialists at UNOS make the final decision as to whether a donor is suitable for a specific recipient.

Living donation

Donation of a body part by a living person is the less common type of organ donation. Usually, but not always, the person who donates is biologically related to the recipient (e.g., parent, sibling, cousin). Related individuals are more likely to have the same blood type and similar immune system markers. This helps prevent organ rejection by the recipient's body. Sometimes a relative is willing to donate an organ, but is not an adequate match for the recipient. In this case, UNOS may be able to arrange a paired organ exchange with another donor-recipient pair. Living donor transplants are slightly more successful (rejected less frequently) than after-death donations.

To be a living donor, the individual cannot have certain diseases such as cancer, HIV infection, hepatitis, or major organ disease. Minors must have parental permission to donate, and all donors undergo extensive medical testing before the donation occurs. The type of body parts that can be donated by a living person include.

- kidney (most common)
- liver (second most common)
- lung
- intestine
- pancreas
- bone marrow

Donation after death

Individuals who want to donate body parts after death should indicate this desire on their driver's license and in a living will or medical directive, as well as making their wishes known to relatives. Donation after death does not disfigure the body and a regular funeral can be held. There is no age limit to donation after death; the suitability of body parts is determined at the time of death. Individuals can specify in advance which organs they want or do not want to donate. Agreeing to donate after death does not compromise the quality of medical care the individual receives before death.

Organs and tissues that can be transplanted after death include:

- kidneys
- liver
- lungs
- heart
- pancreas
- intestines
- cornea
- skin
- bone
- cartilage
- tendons
- ligaments
- veins
- heart valves
- middle ear

Precautions

Living donors undergo extensive medical testing in order to assure that they are healthy enough to make a donation and that the donated material is compatible with the recipient, as organ and tissue rejection is the most common cause for transplant failure.

WWW.BOOKBAZ.IR

KEY TERMS

Cornea—The clear tissue covering the eye.

Pancreas—A gland near the liver and stomach that secretes digestive fluid into the intestine and the hormones insulin and glucagon into the bloodstream.

Preparation

Living donors receive counseling and must sign a statement of informed consent. Minors must have parental consent to be living donors. Living donors receive a standard pre-operative work up as well as extensive cross matching with the recipient to assure tissue compatibility.

Individuals who wish to donate after death should make this known in advance in writing as well as informing their families and their doctors.

Aftercare

The length of the hospital stay and specific aftercare for living donors depends on the organ donated.

Risks

For living donors, the risks are the same as with any operation, mainly infection at the surgical site, uncontrolled bleeding, and adverse reaction to **anesthesia**. People can live healthy, active lives after donating a kidney, lung, or part of a liver or pancreas. There is always the risk, however, that damage by disease or injury to the remaining organ may result in medical problems.

Results

The benefit to the recipient is an extended and improved life. Many living donors and the families of deceased donors find satisfaction in knowing that their donation has given the gift of life to another person.

Tish Davidson, AM

Organic food

Definition

In the United States, organic is a term used for food produced without using most conventional pesticides, fertilizers made with synthetic ingredients or sewage sludge, bioengineering, or ionizing radiation. Organic animal products come from animals that have been fed 100% organic feed and raised without the use of growth hormones or **antibiotics** in an environment where they may or may not have access to the outdoors. Standards for organic foods vary from country to country. The requirements in Canada, Japan, Western Europe, and other developed countries are similar to those in the United States. These countries require special certifications in order to market food as being organic. In the United States, the National Organic Program (NOP) is the federal regulatory organization that governs organic food. The NOP is within the U.S. Department of Agriculture (USDA), which is responsible for administering and enforcing the federal regulations. However, many developing countries have limited standards for certifying food as "organic."

Pesticides in fruits and vegetables

Highest level	Lowest level
Peaches	Onions
Apples	Avocados
Sweet bell peppers	Corn, sweet, frozen
Celery	Pineapples
Nectarines	Mango
Strawberries	Peas, sweet, frozen
Cherries	Kiwi
Pears	Bananas
Grapes, imported	Cabbage
Spinach	Broccoli
Lettuce	Papaya
Potatoes	Blueberries

SOURCE: Developed by the Environmental Working Group

(Table by PreMediaGlobal. © Cengage Learning®.)

Purpose

Through the U.S. Department of Agriculture (USDA), the NOP and the Organic Foods Production Act are intended to assure consumers that the organic foods they purchase are produced, processed, and certified to be consistent with national organic standards.

Organic foods are thought to promote health in humans by eliminating toxins in foods. In addition, the process of growing organic food helps to conserve soil health and water resources, a benefit to the ecological health of our world and its inhabitants. With healthy soil, the surrounding ecosystems are healthier, including birds, animals, and other living organisms. Organic foods helps to reduce agriculture's impact on the environment when farming practices are done in the true sense of organic, sustaining agricultural methods.

The goals of the organic food movement are to:

- improve human health by decreasing the level of chemical toxins in food
- decrease the level of agricultural chemicals in the environment, especially in groundwater
- promote sustainable agriculture
- promote biodiversity
- promote genetic diversity among plants and animals by rejecting genetically modified organisms (GMOs)
- provide fresh, healthy, safe food at competitive prices

Description

Organic foods comprise less than 2% of total food sales in the world. However, the growing and consumption of organic foods is far outpacing non-organic foods. According to the World of Organic Agriculture (WOA), the number of acres used for organic farming totaled about 37.2 million hectares (91.9 million acres) in 2009. The countries with the largest number of organically managed land were Australia, Argentina, and the United States. The largest increase of land being converted to organic farming occurred in Europe. The WOA stated that global organic sales totaled $23 billion in 2002, $50.9 billion in 2008, and $64 billion in 2012. The countries with the largest sales of organic food were the United States, Germany, and France, though the highest per capita consumption of organic foods was in Denmark, Switzerland, and Austria. In the United States, according to the WOA, sales of organic food and beverages increased from $1 billion in 1990 to $26.7 billion in 2010. Organic fruits and vegetables represented the highest growth in sales in 2010 for organic food when compared to the previous year. Organic food sales, as of 2012, represented 4.2% of all U.S. food sales, up from 4% in 2010.

Origins

Organic farming is the oldest method of farming. Before the 1940s, what is today called organic farming was the standard method of raising crops and animals. World War II (1939–1045) accelerated research into new chemicals that could be used either in fighting the war or as replacements for resources that were in short supply because of their usefulness to the military. After the war ended, many of the new technological discoveries were applied to civilian uses, and synthetic fertilizers, new insecticides, and herbicides became available. Fertilizers increased the yield per acre and pesticides encouraged the development of single-crop mega-farms, resulting in the consolidation of agricultural land and the decline of the family farm.

Organic farming, although only a tiny part of American agriculture, originally offered a niche market for smaller, family-style farms. In the early 1980s, this method of food production began to gain popularity, especially in California, Oregon, and Washington. The first commercial organic crops were vegetables that were usually sold locally at farmers' markets and health food stores.

By the late 1980s, interest in organic food had reached a level of public awareness high enough that the U.S. Congress took action and passed the Organic Food Production Act of 1990. This act established the National Organic Standards Board (NOSB) under the USDA. The NOSB developed regulations and enforcement procedures for the growing and handling of all agricultural products that are labeled "organic." These regulations went into effect on October 21, 2002.

WWW.BOOKBAZ.IR

Since the 1990s, the market for organic food has expanded from primarily fruits and vegetables to eggs, dairy products, meat, poultry, and commercially processed foods. In 2000, for the first time, organic food was purchased more often in mainstream supermarkets than in specialty food outlets. By 2005, every state had some farmland that was certified organic, and some supermarket chains had begun selling their own brand-name organic foods. In 2010, according to the WOA, 54% of organic food was sold in mass-market retail establishments, such as supermarkets and warehouse stores; 39% was sold in natural-product retailers; and 7% was sold in farmers' markets, through the Internet, by mail order, or through other various means.

Certification

Organic certification is voluntary and applies to anyone who sells more than $5,000 worth of organic produce annually. (This exempts most small farmers who sell organic produce from their own farm stands.) If a product carries the USDA Organic Seal indicating that it is "certified organic," it must meet the following conditions:

- The product must be raised or produced under an Organic Systems Plan that demonstrates and documents that the food meets the standards for growing, harvesting, transporting, processing, and selling an organic product.
- The producer and/or processor are subject to audits and evaluations by agents certified to enforce organic standards.
- The grower must have distinct boundaries between organic crops and non-organic crops to prevent accidental contamination with forbidden substances through wind drift or water runoff.
- No forbidden substances can be applied to the land organic food is raised on for three years prior to organic certification.
- Seed should be organic, when available, and never genetically altered through bioengineering.
- Good soil, crop, and animal management practices must be followed to prevent contamination of groundwater or contamination of the product by living pathogens, heavy metals, or forbidden chemicals, and to reduce soil erosion and environmental pollution.

To meet these requirements, organic farmers use natural fertilizers such as composted manure to add nutrients to the soil. They control pests by crop rotation and interplanting. The process of interplanting involves growing several different species of plants in an alternating pattern in the same field to slow the spread of disease. Pest control is also achieved by using natural insect predators, traps, and physical barriers. If these methods do not control pests, organic farmers may apply certain nonsynthetic pesticides made from substances that occur naturally in plants. Weed control is achieved by mulching, hand or mechanical weeding, the use of cover crops, and selective burning.

Animal products that are USDA certified organic must come from animals that are fed only organic feed; are not given growth hormones, antibiotics, or other drugs for the purpose of preventing disease; and have access to the outdoors. (This last requirement is considered rather vague, as regulations set neither a minimum amount of time the animal must spend outdoors nor any minimums concerning the amount of outdoor space available per animal.)

Selecting organic food

The USDA allows three label statements to help consumers determine if a food is organic:

- Labels stating "100% organic" indicate that all of the ingredients in the product are certified organic. These items have the USDA Organic Seal on the label.
- Labels stating "organic" indicate that at least 95% of the ingredients are certified organic. These items also carry the USDA Organic Seal on the label.
- Labels stating "made with organic ingredients" indicate that at least 70% of the ingredients are certified organic. These items are not permitted to have the USDA Organic Seal on the label.
- Items that contain fewer than 70% organic ingredients are not permitted to use either the word "organic" or the USDA Organic Seal on the label.

Consumers may be bewildered by other words on food labels such as "natural" or "grass-fed," which may be confused with organic. Natural and organic are not interchangeable. "Natural" foods are minimally processed foods, but they are not necessarily grown or raised under the strict conditions of organic foods, and the term natural does not have a definition. "Grass-fed" indicates that the livestock were fed natural forage but were not necessarily in open pasture for their entire lives.

Debate continues about the exact requirements to label animal products "cage-free," "free-range," or "open pasture." Cage-free simply means the animals were not kept caged, but it does not necessarily mean that they were raised outdoors or allowed to roam freely. There is no certification process for the designation "cage-free."

Animals can spend as little as five minutes per day outdoors and still be considered "free-range." Animal rights organizations are working to clarify these designations and improve the conditions under which all animals are raised.

Organic foods and health

Certified organic food requires more labor to produce, which generally makes it more expensive than non-certified food. Some consumers buy organic food primarily because the way that it is raised benefits the environment. Others believe absolutely in the health benefits of organic food. A larger group of consumers are uncertain if organic food offers enough health benefits to justify the additional cost.

Discussions of the health benefits of organic food can be varied. Advocates of buying organic foods firmly believe that they are preserving their health by protecting their bodies from chemicals that may cause cancer, **asthma**, and other chronic diseases, as well as the earth's health. Non-organic food buyers take the position that the level of pesticide and fertilizer residues in non-organic food is small and harmless. Others follow this thought, and but feel that it is more important to buy locally than purchase organic products from different countries where much energy has been used in the transport of the organic food. Studies comparing organic and non-organic foods have drawn the following conclusions:

- The food supply in the United States, whether organic or non-organic, is extremely safe.
- Fresh organic and non-organic produce are equally likely to become contaminated with pathogens such as *Escherichia coli* (*E. coli*) that cause health concerns.
- Many, but not all, chemical contaminants can be removed from non-organic food by peeling or thoroughly washing in cool, running water.
- Organic foods are not 100% pesticide and chemical free. However, their chemical load appears to be lower than that of non-organic foods.
- The nutrient value of identical organic and non-organic foods may be the same.
- The long-term effect on humans of trace amounts of hormones, antibiotics, and drugs found in milk, meat, and other non-organic animal products is unclear.
- The long-term effect of genetically modified foods on both humans and the environment cannot yet be known.

Growing organic foods

To best prepare land for the growing of organic foods, a wide variety of microbes, fungi, worms, and other live soil organisms are necessary. Synthetic pesticides and herbicides often kill such helpful organisms. In addition, soil needs organic matter, compost, and mulch to make the most for growing organics. Depending on what food is being grown in a field, certain nature elements in a specific concentration are more important than others. A soil test is normally performed before planting to determine what needed elements are missing or lacking.

Precautions

Eating organic food does reduce the risk of consuming pesticides, artificial chemicals, synthetic fertilizers, antibiotics, growth hormones, and other contaminates. Organic foods are produced using environmentally friendly methods and are free from genetically modified ingredients. However, consuming organic food does not completely eliminate the risk of consuming these contaminates. In addition, individuals should be informed about food labeling requirements and read food labels carefully so that they can make informed decisions about their purchases.

Complications

No complications are expected from eating organic food. However, consumers should still be cautious when eating any foods they may already be allergic to, such as peanuts, that cause medical problems in some children. People consuming organic meats should ensure that it is cooked properly to decrease the risk of foodborne illnesses.

Parental concerns

Chemicals found in traditionally grown foods may have a greater effect on the growth and development of younger children than older ones. Young children are rapidly growing while still developing their nervous system, immune system, and other organs. Chemicals may have a greater effect on these developing tissues than on adult tissues.

Research and general acceptance

The health benefits of consuming organically produced foods compared with conventional foods are unclear. Personal health is one of the main reasons for consumers to buy organic; however, scientific evidence for a health effect is still limited. It is also hard to define the benefits of diet or lifestyle since it has been

WWW.BOOKBAZ.IR

KEY TERMS

Biodiversity—The range of organisms present in a defined ecological system.

Genetic engineering—A type of engineering that concentrates on the process of altering genetic material by technical means.

Heavy metals—Any metal with a high relative density that is often toxic to organisms, examples include lead, mercury, and copper.

Pathogen—A living organism that can cause disease, such as a bacterium or virus.

Synthetic—Made with an artificial chemical process, often to resemble a natural product.

shown that people switching to organic foods often eat more freshly prepared foods and have healthier lifestyles than those who do not choose organic.

Studies do show evidence of improved nutrient profiles in organic foods. Recent studies show that dairy products contain significantly higher protein, alpha linolenic acid, total omega-3 fatty acid, cis-9, trans-11 conjugated linoleic acid, trans-11 vaccenic acid, eicosapentaenoic acid, and docosapentaenoic acid, all which have been shown beneficial to overall health, than those of conventionally produced dairy products. In other studies, they show higher levels of micronutrients in organic foods more often than in conventional foods, and the total micronutrient content, to also be higher in organic as compared to conventionally grown produce. The micronutrient content of food groups was more frequently reported to be higher for organic vegetables and legumes compared to their conventional counterparts. More research is needed to show if these increases in nutrient value relate to an increase in overall health benefits.

Orthodontics

Definition

Orthodontics is a specialized branch of dentistry that diagnoses, prevents, and treats dental and facial irregularities called malocclusions. Orthodontics includes dentofacial orthopedics, which is used to correct problems involving the growth of the jaw.

Purpose

Humans have attempted to straighten teeth for thousands of years before orthodontics became a dental specialty in 1900. Although orthodontic treatment often improves facial appearance and occasionally is performed for solely cosmetic reasons, it is used primarily to correct health problems and to ensure the proper functioning of the mouth. Properly aligned teeth, which close together correctly, simplify **oral hygiene** and enable children to chew their food efficiently. Orthodontic treatment provides the following:

- straightens teeth that are rotated, tilted, or otherwise improperly aligned
- corrects crowded or unevenly spaced teeth
- corrects bite problems
- aligns the upper and lower jaws

Malocclusions

Few children have perfectly symmetrical teeth and a perfect bite. In an ideal bite, the following are characteristics:

- All of the teeth fit easily without crowding or spacing.

Orthodontic braces on the teeth of an 11-year old patient. *(© iStockPhotocomBanksPhotos)*

- The teeth are not rotated, twisted, or leaning forward or backward.
- The teeth of the upper jaw slightly overlap those of the lower jaw.
- The points of the molars fit into the grooves of the opposite molars.

Types of malocclusions include the following:

- crowded, crooked, or misaligned teeth
- extra or missing teeth
- bite problems
- jaws that are out of alignment

Causes of malocclusion

Most malocclusions are caused by hereditary factors that affect the contours of the face and the size of the teeth and jaw. The most common cause of **malocclusion** is a disproportion in size between the jaw and teeth or between the upper and lower jaws. A child who inherits a mother's small jaw and a father's large teeth may have teeth that are too big for the jaw, causing overcrowding. Specific inherited malocclusions include:

- overcrowded teeth
- too much space between teeth
- extra or missing teeth
- various irregularities in the teeth, jaw, or face

Malocclusions can be acquired through the following:

- accidents such as a jaw fracture that causes misalignment
- prolonged sucking on thumbs, fingers, or pacifiers, particularly after the age of four

WWW.BOOKBAZ.IR

- fingernail or lip biting
- a lost tooth that causes nearby teeth to move into the empty space, throwing them out of alignment
- airways that are obstructed by tonsils or adenoids
- dental disease
- tumors in the mouth or jaw
- improperly fitted fillings, crowns, or braces
- premature loss of baby teeth or permanent teeth
- late loss of baby teeth

Symptoms of malocclusion

Occasionally children have mild, temporary symptoms of malocclusion resulting from a growth spurt. However, symptoms of malocclusion usually develop gradually beginning at the age of six. Symptoms may include the following:

- crowded or misaligned teeth
- abnormal spacing between teeth, most often occurring because teeth are small or missing or the dental arch (the arch-shaped jawbone that supports the teeth) is very wide
- incisors (front teeth) that do not meet
- an open bite, occurring when the upper and lower incisors do not touch each other during biting, thereby putting all of the chewing pressure on the back teeth and resulting in inefficient chewing and excessive tooth wear
- an overbite or overjet, in which the upper incisors protrude, often caused by a lower jaw that is significantly shorter than the upper jaw
- a deep or closed bite, an excessive overbite in which the lower incisors bite too closely to or into the gum tissue or palate behind the upper teeth
- a crossbite, in which a protruding lower jaw that is longer than the upper jaw causes the upper front or back teeth to bite inside the lower teeth

Early intervention

Although orthodontic treatment can be performed at any age, children are easier, faster, and less expensive to treat than adults. Most often orthodontic treatment is used on older children and adolescents whose teeth are still developing. However some types of problems are corrected more readily before all of the permanent teeth have erupted and facial growth is complete. If a child's permanent lower incisors erupt behind each other, braces may be required at a young age. Crossbites are usually treated early because they can interfere with biting and chewing. Early treatment also is used when thumb- or finger-sucking has affected teeth positioning.

Early orthodontic intervention can provide the following:

- straighten crooked teeth
- preserve or create space for incoming permanent teeth
- guide erupting permanent teeth into the correct positions
- prevent impacted permanent teeth, those that remain partially covered by gum tissue, or partially or completely buried in the jawbone
- correct harmful habits such as thumb- or finger-sucking
- lower the risk of accidents to protruding upper incisors

Other advantages of early orthodontic treatment include the following:

- correction of bite problems by guiding jaw growth and controlling the width of the upper and lower dental arches
- reduction or elimination of abnormal swallowing or speech problems
- shortening and simplification of later orthodontic treatment
- prevention of later tooth extractions
- improvements in appearance and self-esteem

Untreated malocclusions

Minor misalignment or crowding may not require treatment. However untreated malocclusions can cause the following:

- teeth that are partially impacted or fail to erupt
- lips, tongue, or cheeks that contact biting surfaces due to poor tooth alignment
- inefficient or uncomfortable biting, chewing, and digestion
- speech impairments
- teeth that are hard to clean, leading to cavities and gum disease
- abnormal wear of tooth surfaces
- chipped teeth
- loosening or fracturing of a misaligned tooth that is overstrained
- injury to a protruding upper incisor
- thinning and receding of bone and gums covering the roots of very crowded teeth
- accelerated gum disease and bone loss

- temporomandibular joint (TMJ) misalignments at the point where the lower jaw attaches to the skull
- stress and trauma to the teeth, gum tissue, ligaments, muscles, jawbone, and jaw joints
- premature loss of teeth
- adverse effects on facial development and appearance
- the need for surgery

Untreated malocclusions often worsen with time. TMJ problems can cause chronic headaches or **pain** in the face and neck. A deep overbite can cause significant pain and bone damage and may contribute to excessive wear on the incisors.

Orthodontics in young children

Alignment problems usually become apparent as the permanent teeth begin erupting at about age six. Dentists monitor the development of a child's permanent teeth and refer the child to an orthodontist if a problem is suspected. The American Association of Orthodontists recommends that all children be screened by an orthodontist by the age of seven.

Once a child's lower baby incisors have erupted, an orthodontist can measure the child's jaw and tooth size, project their growth rate, and possibly predict whether the child will have orthodontic problems with their permanent teeth. The orthodontist may be able to perform preventative or interceptive orthodontics that can reduce or eliminate the need for braces later.

In a procedure called selective serial extraction, the orthodontist removes one or more baby or permanent teeth. Doing so creates space for the permanent teeth, especially unerupted canine teeth that might become impacted or erupt in the wrong position. After the removal or loss of a tooth, braces or another orthodontic appliance may be used to prevent the remaining teeth from moving into the empty space. If a baby molar that acts as a space-holder for later permanent teeth is lost, a fixed orthodontic wire is inserted between the teeth to keep the space available.

Preparation

The orthodontist compiles pretreatment records that are used for diagnosis, determining the course of treatment, and measuring the progress of treatment. These records may include:

- a complete medical and dental history
- a clinical examination
- x rays revealing the positions of erupted and unerupted teeth, development of unerupted teeth, any missing or impacted teeth, shortened or damaged tooth roots, and the amount of bone supporting the teeth
- a facial-profile x ray or cephalometric film revealing the sizes, positions, and relationships of the teeth and jaw, as well as facial form, growth pattern, and the inclinations of tipped or tilted incisors
- plastic impressions of the bite and plaster models made from the impressions
- photographs and other measurements of the teeth and face

Based on the diagnosis the orthodontist develops a custom treatment plan and designs the appropriate corrective appliances that will gradually straighten or move the teeth. Severe overcrowding may necessitate the extraction of permanent teeth, usually the premolars, to create space prior to using braces to move teeth.

Braces and other orthodontic appliances

By applying constant gentle pressure in a specific direction, braces can slowly move teeth through the supporting bone to a new position. Springs and wires put pressure on teeth in order to straighten them. The pressure causes bone in the jaw to dissolve in front of the moving tooth as new bone grows behind the tooth. Braces and other appliances may be removable or fixed and are made of clear or colored metal, ceramic, or plastic. Removable appliances are often plastic plates that fit into the roof of the mouth and clip onto a tooth.

Fixed braces exert more pressure than removable braces and can achieve more complex movements. They consist of wires and springs that are held in place by small brackets glued to the outside surfaces of the incisors and sometimes the premolars. Lingual braces have brackets bonded to the back of the teeth. Bands encircling the molars also can be used for attachments. The wires, springs, and other devices attached to the brackets or bands put pressure on the teeth, gradually shifting them into new positions. The nickel-titanium wires are very light, and some are heat-activated. These are very flexible at room temperature and actively begin to move the teeth as they warm to body temperature. Elastic bands sometimes connect the upper and lower teeth to create tension.

Appliances used to direct jaw growth and development in growing children and adolescents include:

- Headgear attached to braces and usually worn for 10 to 12 hours at night puts pressure on the upper teeth and jaw and influences the direction and speed of upper jaw growth and upper teeth eruption.

WWW.BOOKBAZ.IR

KEY TERMS

Active treatment stage—The period during which orthodontic appliances or braces are used.

Bicuspid—Premolar; the two-cupped tooth between the first molar and the cuspid.

Canines—The two sharp teeth located next to the front incisor teeth in mammals that are used to grip and tear. Also called cuspids.

Crossbite—The condition in which the upper teeth bite inside the lower teeth.

Crown—The natural part of the tooth covered by enamel. A restorative crown is a protective shell that fits over a tooth.

Deep bite—A closed bite; a deep or excessive overbite in which the lower incisors bite too closely to or into the gum tissue or palate behind the upper teeth.

Eruption—The process of a tooth breaking through the gum tissue to grow into place in the mouth.

Impacted tooth—Any tooth that is prevented from reaching its normal position in the mouth by another tooth, bone, or soft tissue.

Incisors—The eight front teeth.

Interceptive orthodontics—Preventative orthodontics; early, simpler orthodontic treatment.

Malocclusion—The misalignment of opposing teeth in the upper and lower jaws.

Molars—The teeth behind the primary canines or the permanent premolars, with large crowns and broad chewing surfaces for grinding food.

Open bite—A malocclusion in which some teeth do not meet the opposing teeth.

Orthognathic surgery—Surgery to alter the relationships of the teeth and/or supporting bones, usually in conjunction with orthodontic treatment.

Overbite—Protrusion of the upper teeth over the lower teeth.

Plaque—A sticky film of saliva, food particles, and bacteria that attaches to the tooth surface and causes decay.

Retainer—An orthodontic appliance that is worn to stabilize teeth in a new position.

Retention treatment stage—The passive treatment period following orthodontic treatment, when retainers may be used to stabilize the teeth.

Temporomandibular joint (TMJ)—One of a pair of joints that attaches the mandible of the jaw to the temporal bone of the skull. It is a combination of a hinge and a gliding joint.

- Herbst appliances attached to the upper and lower molars correct a severe overbite by holding the lower jaw forward, influencing jaw growth and tooth position; they force the jaw muscles to work in ways that promote forward development of the lower jaw; treatment with Herbst appliances must begin several years before the jaw stops growing and they must remain in place throughout the treatment.
- Palatal or upper jaw expansion devices can widen a narrow upper jaw and correct a crossbite within months.
- Removable bionators hold the lower jaw forward and guide tooth eruption while helping the upper and lower jaws to grow proportionately.

Headgear and Herbst appliances can significantly reduce protrusion of the four top incisors and enable the growing lower jaw to catch up with the upper jaw, eliminating swallowing problems.

Duration of treatment

Orthodontic treatment usually continues until the desired outcome is reached. Active orthodontic treatment lasts an average of two years, with a range of one to three years. Some children respond to treatment faster than others and interceptive or early treatments may continue for only a few months. Appliances are adjusted periodically during treatment. Factors affecting the duration of treatment include:

- the growth of the mouth and face
- the severity of the problem
- the health of the teeth, gums, and supporting bones
- the child's level of cooperation

Precautions

Orthodontic appliances trap food, bacteria, and plaque, leading to **tooth decay**. Extra brushing with specially shaped and/or electric toothbrush and fluoride toothpaste is required around the areas where the braces or appliances attach to the teeth. Both the tops and bottoms of braces must be brushed and irrigated with a water jet directed from the top down and the bottom up. If possible, teeth should be flossed. A fluoride mouthwash may be recommended. Removable appliances should be brushed every time the teeth

are brushed. Regular dental check-ups and cleanings must be continued.

Children with braces should eat raw fruits and vegetables and avoid soft, processed, and refined foods that attract bacteria, as well as hard or sticky foods, including gum, caramels, peanuts, ice chips, and popcorn. Chewing on hard items, such as fingernails or pencils, can damage braces. Children with braces should wear a protective mouth guard while playing contact sports.

Aftercare

After braces are removed the teeth must be stabilized in their new positions. This phase of treatment commonly takes two to three years. Occasionally it continues indefinitely. Types of retainers used for stabilization include:

- positioners, rubber-like mouthpieces that are worn at night and bitten into for a few hours during the day
- removable retainers with a plastic plate that snaps onto the roof of the mouth and wires on the outside of the teeth
- removable, clear, plastic retainers that completely cover the sides and biting surfaces of the teeth
- semi-rigid wires that are bonded onto the inside of the incisors.

Results

Orthodontic treatment is usually very successful at correcting malocclusions. Even a significant size discrepancy between the upper and lower jaws often can be corrected. Sometimes, particularly in adults, corrective orthognathic surgery is required to shorten or lengthen a jawbone. The height of the lower face also can be shortened or lengthened. Sometimes surgery reduces the duration of the orthodontic treatment.

Maturational change can cause teeth to gradually shift with age—at least until one's early 20s—causing crowding. Nighttime retainers can prevent maturational movement.

Risks

Braces may cause discomfort when they are first installed or adjusted during treatment. For the first three to five days teeth may hurt during biting. Lips, cheeks, and tongue may be irritated for one to two weeks before they toughen and adapt to the braces. Some appliances may interfere with speech for the first day or two. Damaged appliances can extend the length of treatment and negatively affect the outcome.

Food particles and plaque deposits around orthodontic appliances can cause demineralization of the tooth enamel, leading to cavities and permanent whitish **scars** on the teeth.

Parental concerns

In general the earlier an orthodontic problem is detected, the easier and less expensive it is to correct. Parents can compare their child's dental development with standard charts and pictures.

Children with problems involving the width or length of the jaws should be evaluated no later than age 10 for girls and age 12 for boys. For children receiving orthodontic care, the orthodontist should be notified immediately if an appliance breaks. Indications that children may need an early orthodontic examination include:

- early or late loss of baby teeth
- crowded, misplaced, or blocked-out teeth
- upper and lower teeth that do not meet normally
- thumb- or finger-sucking
- biting of the cheek or roof of the mouth
- difficulty biting or chewing
- breathing through the mouth
- jaws that shift or make noise
- jaws and teeth that are out of proportion to the rest of the face

KEY TERMS

Arthroplasty—The surgical reconstruction or replacement of a joint.

Prosthesis—A synthetic replacement for a missing part of the body such as a knee or a hip.

Range of motion—The normal extent of movement (flexion and extension) of a joint.

Orthopedic surgery

Definition

Orthopedic (sometimes spelled orthopaedic) surgery is an operation performed by a medical specialist such as an orthopedist or orthopedic surgeon, who is trained to assess and treat problems that develop in the bones, joints, and ligaments of the human body.

Description

The range of treatments provided by orthopedists is extensive. They include procedures such as **traction**, **amputation**, hand reconstruction, **spinal fusion**, and joint replacements. They also treat strains and sprains, broken bones, and **dislocations**.

In general, orthopedists are employed by hospitals, medical centers, **trauma** centers, or free-standing surgical centers where they work closely with a surgical team, including an anesthesiologist and surgical nurse. Orthopedic surgery can be performed under general, regional, or local **anesthesia**.

Much of the work of an orthopedic surgeon involves adding foreign material to the body in the form of screws, wires, pins, tongs, and **prosthetics** to hold damaged bones in their proper alignment or to replace damaged bone or connective tissue. Great improvements have been made in the development of artificial limbs and joints and in the materials available to repair damage to bones and connective tissue. As developments occur in the fields of metallurgy and plastics, changes take place in orthopedic surgery that allow surgeons to more nearly duplicate the natural functions of bones, joints, and ligaments and to more accurately restore damaged parts to their original ranges of motion.

Purpose

Orthopedic surgery addresses and attempts to correct problems that arise in the skeleton and its attachments, the ligaments and tendons. It may also include some problems of the nervous system, such as those that arise from injury of the spine. These problems can occur at birth, through injury, or as the result of **aging**. They may be acute, as in an accident or injury, or chronic, as in many problems related to aging.

Orthopedics comes from two Greek words, *ortho*, meaning straight, and *pais*, meaning child. Originally, orthopedic surgeons treated skeletal deformities in children, using braces to straighten the child's bones. With the development of anesthesia and an understanding of the importance of aseptic technique in surgery, orthopedic surgeons extended their role to include surgery involving the bones and related nerves and connective tissue.

The terms orthopedic surgeon and orthopedist are used interchangeably to indicate a medical doctor with special training and certification in orthopedics.

Many orthopedic surgeons maintain a general practice; however, some specialize in one particular aspect of orthopedics such as hand surgery, joint replacements, or disorders of the spine. Orthopedists treat both acute and chronic disorders. Some orthopedic surgeons specialize in trauma medicine and can be found in emergency rooms and trauma centers, treating injuries. Others find their work overlapping with plastic surgeons, geriatric specialists, pediatricians, or podiatrists (**foot care** specialists). One growing area of orthopedics is sports medicine, and many sports medicine doctors are board certified in orthopedic surgery.

Preparation

Persons are usually referred to an orthopedic surgeon by a primary care physician, emergency room physician, or other doctor. Prior to surgery, candidates undergo extensive testing to determine appropriate corrective procedures. Tests may include x rays, computed tomography (CT) scans, **magnetic resonance imaging** (MRI), myelograms, diagnostic **arthroplasty**, and blood tests. The orthopedist determines the history of the disorder and any treatments that were previously

tried. A period of rest to the injured part may be recommended before surgery is undertaken.

Surgical candidates undergo standard blood and urine tests before surgery and, for major procedures, may be given an electrocardiogram or other diagnostic tests prior to the operation. Individuals may choose to donate some of their own blood to be held in reserve for their use in major surgery such as **knee replacement**, during which heavy bleeding is common.

Aftercare

Rehabilitation from orthopedic injuries can require long periods of time. Rehabilitation is usually physically and mentally taxing. Orthopedic surgeons work closely with physical therapists to ensure that patients receive treatment that enhances the range of motion and return function to all affected body parts.

Results

Thousands of people have successful orthopedic surgery each year to recover from injuries or to restore lost function. The degree of success in individual recoveries depends on an individual's age and general health, the medical problem being treated, and a person's willingness to comply with rehabilitative therapy after the surgery.

Abnormal results from orthopedic surgery include persistent **pain**, swelling, redness, drainage or bleeding in the surgical area, surgical wound infection resulting in slow healing, and incomplete restoration of pre-surgical function.

Risks

As with any surgery, there are risks of excessive bleeding, infection, and allergic reaction to anesthesia. Risks specifically associated with orthopedic surgery include inflammation at the site where foreign materials (pins, prostheses, or wires) are introduced into the body, infection as the result of surgery, and damage to nerves or to the spinal cord.

Orthostatic hypotension

Definition

Orthostatic **hypotension** is an abnormal decrease in blood pressure when a person stands up. This may lead to **fainting**.

Description

When a person stands upright, a certain amount of blood normally pools in the veins of the ankles and legs. This pooling means that there is slightly less blood for the heart to pump and causes a drop in blood pressure. Usually, the body responds to this drop so quickly, a person is unaware of the change. The brain tells the blood vessels to constrict so they have less capacity to carry blood, and at the same time tells the heart to beat faster and harder. These

WWW.BOOKBAZ.IR

responses last for a very brief time. If the body's response to a change in vertical position is slow or absent, the result is orthostatic hypotension. It is not a true disease, but the inability to regulate blood pressure quickly.

Causes and symptoms

Orthostatic hypotension has many possible causes. The most common cause is medications used to treat other conditions. **Diuretics** reduce the amount of fluid in the body which reduces the volume of blood. Medicines used to expand the blood vessels increase the vessel's ability to carry blood and so lower blood pressure.

If there is a severe loss of body fluid from **vomiting**, **diarrhea**, untreated diabetes, or even excessive sweating, blood volume will be reduced enough to lower blood pressure. Severe bleeding can also result in orthostatic hypotension.

Any disease or **spinal cord injury** that damages the nerves which control blood vessel diameter can cause orthostatic hypotension.

Symptoms of orthostatic hypotension include faintness, **dizziness**, confusion, or blurry vision, when standing up quickly. An excessive loss of blood pressure can cause a person to pass out.

Diagnosis

When a person experiences any of the symptoms above, a physician can confirm orthostatic hypotension if the person's blood pressure falls significantly on standing up and returns to normal when lying down. The physician will then look for the cause of the condition.

Treatment

When the cause of orthostatic hypotension is related to medication, it is often possible to treat it by reducing dosage or changing the prescription. If it is caused by low blood volume, an increase in fluid intake and retention will solve the problem.

Medications designed to keep blood pressure from falling can be used when they will not interfere with other medical problems.

When orthostatic hypotension cannot be treated, the symptoms can be significantly reduced by remembering to stand up slowly or by wearing elastic stockings.

Prognosis

The prognosis for people who have orthostatic hypotension depends on the underlying cause of the problem.

Prevention

There is no way to prevent orthostatic hypotension, since it is usually the result of another medical condition.

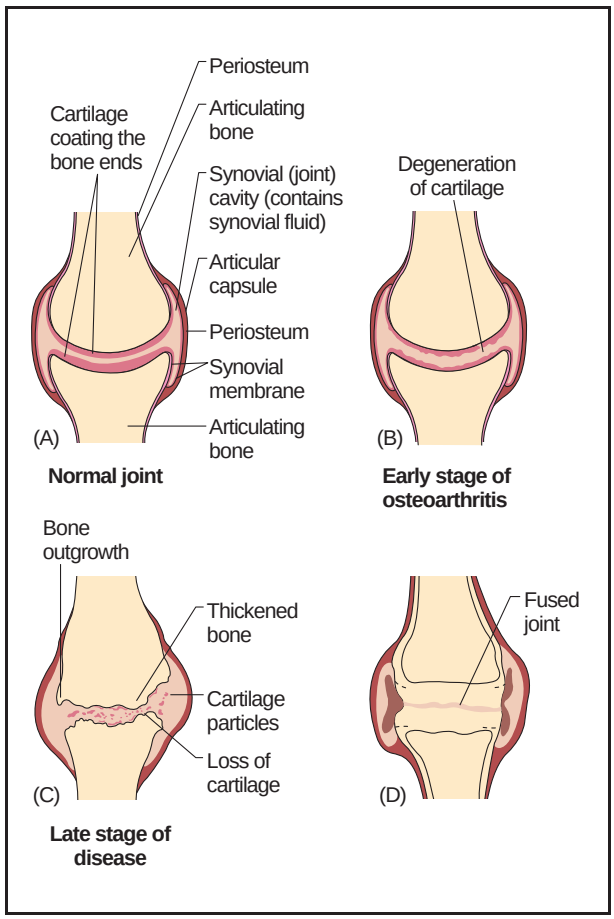
Osteoarthritis

Definition

Osteoarthritis is a degenerative joint disease characterized by the breakdown of the joint's cartilage.

Demographics

According to the American College of Rheumatology, osteoarthritis affects people of all ages, but is more common in older populations, with 70% of people over the age of 70 showing x-ray evidence of the disease. Of this number, only half ever develop symptoms. Before age 45, more men than women have osteoarthritis; after age 45, it is more common in women, affecting especially their fingers and knees. The condition is also more likely to occur in people who are overweight and in people with jobs that **stress** particular joints. As of 2014, the National Institute of Arthritis and Musculoskeletal and Skin Diseases



The progression of osteoarthritis. *(Illustration by Hans & Cassady, Inc. © Cengage Learning®.)*

(NIAMS) estimates that osteoarthritis is by far the most common type of arthritis, with some 12.1% of Americans (nearly 27 million) aged 25 and older affected. By 2030, 20% of Americans, or some 72 million people, will be older than 65 and will be at high risk for the disease.

Studies are indicative of some ethnic and geographical differences in prevalence. African American females are more prone than Caucasian females to osteoarthritis of the knee, but not for the hip. Osteoarthritis of the hip occurs more often in European Caucasians than in Jamaican blacks, African or South African blacks, Chinese, or Asian Indians.

Description

Osteoarthritis is one of the oldest and most common types of arthritis that mostly affects cartilage, the slippery part of the joint that cushions the ends of bones. Unlike some other types of arthritis, osteoarthritis affects only joints and not internal organs. With the breakdown of cartilage, bones rub against each other, causing **pain** and loss of movement. Over time, the affected joint may lose its normal shape. Also, bone spurs may grow on the edges of the joint. Bone or cartilage can break off and migrate inside the joint space, causing more pain and damage.

Osteoarthritis can occur in any joint, but commonly affects hands, knees, hips or spine.

Risk factors

Age increases the risk of osteoarthritis, which typically occurs in older adults. Women are also more likely to develop osteoarthritis. People born with malformed joints or defective cartilage are also at increased risk. **Obesity** is another factor, as more body weight places more stress on weight–bearing joints. Diseases such as **gout**, **rheumatoid arthritis**, Paget's disease of bone or septic arthritis can also increase the risk of developing osteoarthritis.

People with joint injuries from sports, work–related activity, or accidents may also be at increased risk. Individuals with mismatched surfaces on the joints that could be damaged over time by abnormal stress may be prone to osteoarthritis. One study reported that wearing shoes with 2.5 in (6.3 cm) heels or higher may also be a contributing factor. High heels force women to alter the way they normally maintain balance, putting strain on the areas between the kneecap and thigh bone and on the inside of the knee joint.

Causes and symptoms

The biological causes of the disorder are currently unknown. Although osteoarthritis is generally more prevalent in the older population, it does not appear to be caused by **aging** itself, since osteoarthritic cartilage has been shown to be chemically different from normal aged cartilage.

Genetics plays a role in the development of osteoarthritis, particularly in the hands and hips. One study found that heredity may be involved in 30% of people with osteoarthritic hands and 65% of those with osteoarthritic knees. Another study found a higher correlation of osteoarthritis between parents and children and between siblings than between spouses. Other research has shown that a genetic abnormality may promote a breakdown in the protective structure of cartilage.

Abnormal collagen genes have been identified in some families with osteoarthritis. One recent study found that the type IX collagen gene COL9A1 (6q12–q13) may be a susceptibility locus for female

WWW.BOOKBAZ.IR

KEY TERMS

Cartilage—Supportive connective tissue which cushions bone at the joints or which connects muscle to bone.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Corticosteroids—Anti-inflammatory medications. Related to cortisol, a naturally produced hormone that controls many body functions.

hip osteoarthritis. Other research has suggested that mutations in the COL2A1 gene may be associated with osteoarthritis.

Some evidence also suggests that a female–specific susceptibility gene for idiopathic osteoarthritis is located on 11q. There is some evidence of genetic abnormality at the IL1R1 marker on gene 2q12 in individuals with severe osteoarthritis and Heberden nodes (bony lumps on the end joint of fingers).

Although many people over 70 show evidence of osteoarthritis on x ray, only 50% experience symptoms. Symptoms range from very mild to very severe, affecting hands and weight–bearing joints such as knees, hips, feet, and the back. The pain of osteoarthritis usually begins gradually and progresses slowly over many years.

Osteoarthritis is commonly identified by aching pain in one or more joints, stiffness, and loss of mobility. The disease can cause significant trouble walking and stair climbing. Inflammation may or may not be present. Extensive use of the joint often exacerbates pain in the joints. Osteoarthritis is often more bothersome at night than in the morning and in humid weather than dry weather. Periods of inactivity, such as sleeping or sitting, may result in stiffness, which can be eased by stretching and **exercise**. Osteoarthritis pain tends to fade within a year of appearing.

Bony lumps on the end joint of the finger, called Herberden's nodes, and on the middle joint of the finger, called Bouchard's nodes, may also develop.

Diagnosis

Examination

A diagnosis of osteoarthritis is made based on a physical exam and history of symptoms.

It is possible to distinguish osteoarthritis from other joint diseases by considering a number of factors together:

- Osteoarthritis usually occurs in older people.
- It is usually located in only one or a few joints.
- The joints are less inflamed than in other arthritic conditions.
- Progression of pain is almost always gradual.

A few of the most common disorders that might be confused with osteoarthritis are rheumatoid arthritis, chondrocalcinosis, and Charcot's joints.

Tests

X rays are used to confirm diagnosis. In people over 60, the disease can often be observed on x ray. An indication of cartilage loss arises if the normal space between the bones in a joint is narrowed, if there is an abnormal increase in bone density, or if bony projections or erosions are evident. Any cysts that might develop in osteoarthritic joints are also detectable by x ray.

Additional tests can be performed if other conditions are suspected or if the diagnosis is uncertain. Blood tests can rule out rheumatoid arthritis or other forms of arthritis. Synovial fluid analysis may also be performed to detect crystals that may be present in the joint and to look for signs of joint infection. MRI (**magnetic resonance imaging**) may also be used to examine affected joints.

Treatment

There is no known way to prevent osteoarthritis or slow its progression. Some lifestyle changes can reduce or delay symptoms. Treatment often focuses on decreasing pain and improving joint movement. Prevention and treatment measures may include:

- Exercises to maintain joint flexibility and improve muscle strength. By strengthening the supporting muscles, tendons, and ligaments, regular weight–bearing exercise helps protect joints, even possibly stimulating growth of the cartilage.
- Joint protection, which prevents strain and stress on painful joints.
- Heat/cold therapy for temporary pain relief.
- Weight control, which prevents extra stress on weight–bearing joints. One study reported that weight loss seemed to reduce the risk for symptomatic osteoarthritis of the knee in women, and in another, women who lost 11 pounds or more cut their risk for developing osteoarthritis in half.

- Surgery may be needed to relieve chronic pain in damaged joints. Osteoarthritis is the most common indication for total joint replacement of the hip and knee.

Drugs

Various pain control medications, including **corticosteroids** and NSAIDs (nonsteroidal anti–inflammatory drugs such as **aspirin**, **acetaminophen**, ibuprofen, and naproxen) are available. For inflamed joints that are not responsive to NSAIDS, injectable glucocorticoids may be used. For mild pain without inflammation, acetaminophen is commonly used.

Alternatives

Clinical trials for the treatment of osteoarthritis are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2014, NIH reported 233 on going studies. Some examples include the following:

- A pilot study of group physical therapy for knee osteoarthritis. (NCT00642772)
- The evaluation of whether implanting gold beads extra–articularly in five acupuncture points around a knee improves pain, stiffness and function in patients with knee osteoarthritis. (NCT00487370)
- The evaluation of the effectiveness of a novel biomechanical device consisting of four individually calibrated elements attached onto foot–worn platforms in reducing pain and improving function in patients with knee osteoarthritis. (NCT00457132)
- The evaluation of certain exercises designed to improve knee stability, reduce pain, and improve physical function in people with knee osteoarthritis. (NCT00078624)

Glucosamine and chondroitin sulfate are popular **nutritional supplements** that may diminish the symptoms of osteoarthritis. According to some reports, a daily dose of 750–1,500 mg of glucosamine and chondroitin sulfate may result in reduced joint pain, stiffness, and swelling, however these supplements are not approved by the U.S. Food and Drug Administration as effective treatment of osteoarthritis. A person with osteoarthritis should consult with a doctor before using dietary supplements to treat symptoms.

Prognosis

Osteoarthritis is not life-threatening, but quality of life can deteriorate significantly due to the pain and loss of mobility that it causes. Advanced osteoarthritis can force the patient to forgo activities, even walking, unless the condition is alleviated by medication or corrected by surgery.

There is no cure for osteoarthritis, and no treatment alters its progression with any certainty. Only **heart disease** has a greater impact on work, and 5% of those who leave the work force do so because of osteoarthritis.

Prevention

Preventive measures include maintaining an ideal body weight, exercising, standing straight, avoiding repetitive stress on the joints, using the strongest joints and muscles to lift or move big objects, and avoiding injuries to joints, as articular cartilage wears away in previously injured joints. It has also been reported that deficiencies in **vitamin D** in older people may worsen their condition, so individuals with osteoarthritis should strive to get the recommended 400 IU a day. To protect bones, adults should also consume at least 1,000 mg of **calcium** daily.

Osteoarthrosis *see* **Osteoarthritis**

Osteochondroses

Definition

Osteochondroses comprise group of diseases of children and adolescents in which localized tissue death (necrosis) occurs, usually followed by full regeneration of healthy bone tissue. The singular term is osteochondrosis.

Description

During the years of rapid bone growth, blood supply to the growing ends of bones (epiphyses) may become insufficient resulting in necrotic bone, usually near joints. The term avascular necrosis is used to describe osteochondrosis. Since bone is normally undergoing a continuous rebuilding process, the necrotic areas are most often self-repaired over a period of weeks or months.

Osteochondrosis can affect different areas of the body and is often categorized by one of three locations: articular, non-articular, and physeal.

Physeal osteochondrosis is known as Scheuermann's disease. It occurs in the spine at the intervertebral joints (physes), especially in the chest (thoracic) region.

Articular disease occurs at the joints (articulations). One of the more common forms is Legg-Calvé-Perthes disease, occurring at the hip. Other forms include Köhler's disease (foot), Freiberg's disease (second toe), and Panner's disease (elbow). Freiberg's disease is the one type of osteochondrosis that is more common in females than in males. All others affect the sexes equally.

Non-articular osteochondrosis occurs at any other skeletal location. For instance, Osgood-Schlatter disease of the tibia (the large inner bone of the leg between the knee and ankle) is relatively common.

Osteochondritis dissecans is a form of osteochondrosis in which loose bone fragments may form in a joint.

Causes and symptoms

Many theories have been advanced to account for osteochondrosis, but none has proven fully satisfactory. **Stress** and ischemia (reduced blood supply) are two of the most commonly mentioned factors. Athletic young children are often affected when they overstress their developing limbs with a particular repetitive motion. Many cases are idiopathic, meaning that no specific cause is known.

The most common symptom for most types of osteochondrosis is simply **pain** at the affected joint,

especially when pressure is applied. Locking of a joint or limited range of motion at a joint can also occur.

Scheuermann's disease can lead to serious **kyphosis** (hunchback condition) due to erosion of the vertebral bodies. Usually, however, the kyphosis is mild, causing no further symptoms and requiring no special treatment.

Diagnosis

Diagnosis can be confirmed by x-ray findings.

Treatment

Conservative treatment is usually attempted first. In many cases, simply resting the affected body part for a period of days or weeks will bring relief. A cast may be applied if needed to prevent movement of a joint.

Surgical intervention may be needed in some cases of osteochondritis dissecans to remove abnormal bone fragments in a joint.

Prognosis

Accurate prediction of the outcome for individual patients is difficult with osteochondrosis. Some patients will heal spontaneously. Others will heal with little treatment other than keeping weight or stress off the affected limb. The earlier the age of onset, the better the prospects for full recovery. Surgical intervention is often successful in osteochondritis dissecans.

Prevention

No preventive measures are known.

Osteogenesis imperfecta

Definition

Osteogenesis imperfecta (OI) is a group of genetic diseases of collagen in which the bones are formed improperly, making them fragile and prone to breaking.

Description

Collagen is a fibrous protein material. It serves as the structural foundation of skin, bone, cartilage, and ligaments. In osteogenesis imperfecta, the collagen produced is abnormal and disorganized. This results in a number of abnormalities throughout the body, the most notable being fragile, easily broken bones.

There are four forms of OI, Types I through IV. Of these, Type II is the most severe, and is usually fatal within a short time after birth. Types I, III, and IV have some overlapping and some distinctive symptoms, particularly weak bones.

Evidence suggests that OI results from abnormalities in the collagen gene COL1A1 or COL1A2, and possibly abnormalities in other genes. In OI Type I, II, and III, the gene map locus is 17q21.31-q22, 7q22.1, and in OI Type IV, the gene map locus is 17q21.31-q22.

In OI, the genetic abnormality causes one of two things to occur. It may direct cells to make an altered collagen protein and the presence of this altered collagen causes OI Type II, III, or IV. Alternately, the dominant altered gene may fail to direct cells to make any collagen protein. Although some collagen is produced by instructions from the normal gene, an overall decrease in the total amount of collagen produced results in OI Type I.

A child with only one parent who is a carrier of a single altered copy of the gene has no chance of actually having the disease, but a 50% chance of being a carrier.

If both parents have OI caused by an autosomal dominant gene change, there is a 75% chance that the child will inherit one or both OI genes. In other words, there is a 25% chance the child will inherit only the mother's OI gene (and the father's unaffected gene), a 25% chance the child will inherit only the father's OI gene (and the mother's unaffected gene), and a 25% chance the child will inherit both parents' OI genes. Because this situation has been uncommon, the outcome of a child inheriting two OI genes is hard to predict. It is likely that the child would have a severe, possibly lethal, form of the disorder.

About 25% of children with OI are born into a family with no history of the disorder. This occurs when the gene spontaneously mutates in either the sperm or the egg before the child's conception. No triggers for this type of mutation are known. This is called a new dominant mutation. The child has a 50% chance of passing the disorder on to his or her children. In most cases, when a family with no history of

WWW.BOOKBAZ.IR

OI has a child with OI, they are not at greater risk than the general population for having a second child with OI, and unaffected siblings of a person with OI are at no greater risk of having children with OI than the general population.

In studies of families into which infants with OI Type II were born, most of the babies had a new dominant mutation in a collagen gene. In some of these families, however, more than one infant was born with OI. Previously, researchers had seen this recurrence as evidence of recessive inheritance of this form of OI. More recently, however, researchers have concluded that the rare recurrence of OI to a couple with a child with autosomal dominant OI is more likely due to gonadal mosaicism. Instead of mutation occurring in an individual sperm or egg, it occurs in a percentage of the cells that give rise to a parent's multiple sperm or eggs. This mutation, present in a percentage of his or her reproductive cells, can result in more than one affected child without affecting the parent with the disorder. An estimated 2–4% of families into which an infant with OI Type II is born are at risk of having another affected child because of gonadal mosaicism.

Demographics

OI affects equal numbers of males and females. It occurs in about one of every 20,000 births.

Causes and symptoms

OI is usually inherited as an autosomal dominant condition. In autosomal dominant inheritance, a single abnormal gene on one of the autosomal chromosomes (one of the first 22 "non-sex" chromosomes) from either parent can cause the disease. One of the parents will have the disease (since it is dominant) and is the carrier. Only one parent needs to be a carrier in order for the child to inherit the disease. A child who has one parent with the disease has a 50% chance of also having the disease.

Type I

This is the most common and mildest type. Among the common features of Type I are the following:

- Bones are predisposed to fracture, with most fractures occurring before puberty; people with OI type I typically have about 20–40 fractures before puberty.
- Stature is normal or near-normal.
- Joints are loose and muscle tone is low.
- Usually sclera (whites of the eyes) have blue, purple, or gray tint.
- Face shape is triangular.
- Tendency toward scoliosis (a curvature of the spine).
- Bone deformity is absent or minimal.
- Dentinogenesis imperfecta may occur, causing brittle teeth.
- Hearing loss is a possible symptom, often beginning in the early 20s or 30s.
- Structure of collagen is normal, but the amount is less than normal.

Type II

Sometimes called the lethal form, Type II is the most severe form of OI. Among the common features of Type II are the following:

- Frequently, OI Type II is lethal at or shortly after birth, often as a result of respiratory problems.
- Fractures are numerous and bone deformity is severe.
- Stature is small with underdeveloped lungs.
- Collagen is formed improperly.

Type III

Among the common features of Type III are the following:

- Bones fracture easily (fractures are often present at birth, and x rays may reveal healed fractures that occurred before birth; people with OI Type III may have more than 100 fractures before puberty).
- Stature is significantly shorter than normal.
- Sclera (whites of the eyes) have blue, purple, or gray tint.
- Joints are loose and muscle development is poor in arms and legs.
- Rib cage is barrel-shaped.
- Face shape is triangular.
- Scoliosis (a curvature of the spine) is present.
- Respiratory problems are possible.
- Bones are deformed and deformity is often severe.
- Dentinogenesis imperfecta may occur, causing brittle teeth.
- Hearing loss is possible.
- Collagen is formed improperly.

Type IV

OI Type IV falls between Type I and Type III in severity. Among the common features of Type IV are the following:

- Bones fracture easily, with most fractures occurring before puberty.

- Stature is shorter than average.
- Sclera (whites of the eyes) are normal in color, appearing white or near-white.
- Bone deformity is mild to moderate.
- Scoliosis (curvature of the spine) is likely.
- Rib cage is barrel-shaped.
- Face is triangular in shape.
- Dentinogenesis imperfecta may occur, causing brittle teeth.
- Hearing loss is possible.
- Collagen is formed improperly.

Diagnosis

It is often possible to diagnose OI solely on clinical features and x-ray findings. Collagen or DNA tests may help confirm a diagnosis of OI. These tests generally require several weeks before results are known. Approximately 10–15% of individuals with mild OI who have collagen testing, and approximately 5% of those who have **genetic testing**, test negative for OI despite having the disorder.

Diagnosis is usually suspected when a baby has bone **fractures** after having suffered no apparent injury. Another indication is small, irregular, isolated bones in the sutures between the bones of the skull (wormian bones). Sometimes the bluish sclera serves as a diagnostic clue. Unfortunately, because of the unusual nature of the fractures occurring in a baby who cannot yet move, some parents have been accused of **child abuse** before the actual diagnosis of osteogenesis imperfecta was reached.

Prenatal diagnosis

Testing is available to assist in prenatal diagnosis. Women with OI who become pregnant, or women who conceive a child with a man who has OI, may wish to explore prenatal diagnosis. Because of the relatively small risk (2–4%) of recurrence of OI Type II in a family, families may opt for **ultrasound** studies to determine if a developing fetus has the disorder.

Ultrasound is the least-invasive procedure for prenatal diagnosis, and carries the least risk. Using ultrasound, a doctor can examine the fetus's skeleton for bowing of the leg or arm bones, fractures, shortening, or other bone abnormalities that may indicate OI. Different forms of OI may be detected by ultrasound in the second trimester. The reality is that when it occurs as a new dominant mutation, it is found inadvertantly on ultrasound, and it may be difficult to know the diagnosis until after delivery since other genetic conditions can cause bowing and/or fractures prenatally.

KEY TERMS

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Ligament—A type of connective tissue that connects bones or cartilage and provides support and strength to joints.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Sclera—The tough white membrane that forms the outer layer of the eyeball.

Scoliosis—An abnormal, side-to-side curvature of the spine.

Chorionic villus sampling is a procedure to obtain chorionic villi tissue for testing. Examination of fetal collagen proteins in the tissue can reveal information about the quantitative or qualitative collagen defects that leads to OI. When a parent has OI, it is necessary for the affected parent to have the results of his or her own collagen test available. Chorionic villus sampling can be performed at 10–12 weeks of **pregnancy**.

Amniocentesis is a procedure that involves inserting a thin needle into the uterus, into the amniotic sac, and withdrawing a small amount of amniotic fluid. DNA can be extracted from the fetal cells contained in the amniotic fluid and tested for the specific mutation known to cause OI in that family. This technique is useful only when the mutation causing OI in a particular family has been identified through previous genetic testing of affected family members, including previous pregnancies involving a baby with OI. Amniocentesis is performed at 16–18 weeks of pregnancy.

Treatment

There are no treatments available to cure OI, nor to prevent most of its complications. Most treatments are aimed at treating the fractures and bone deformities caused by OI. Splints, casts, braces, and rods are all used. Rodding refers to a surgical procedure in which a metal rod is implanted within a bone (usually the long bones of the thigh and leg). This is done when bowing or repeated fractures of these bones has interfered with a child's ability to begin to walk.

Other treatments include **hearing aids** and early capping of teeth. Patients may require the use of a walker or wheelchair. **Pain** may be treated with a variety of medications. **Exercise** is encouraged as a means to

WWW.BOOKBAZ.IR

promote muscle and bone strength. Swimming is a form of exercise that puts a minimal amount of strain on muscles, joints, and bones. Walking is encouraged for those who are able.

Smoking, excessive alcohol and **caffeine** consumption, and steroid medications may deplete bone and exacerbate bone fragility.

Alternative treatment such as **acupuncture**, naturopathic therapies, hypnosis, relaxation training, visual imagery, and **biofeedback** have all been used to try to decrease the constant pain of fractures.

Prognosis

Lifespan for people with OI Type I, III, and IV is not generally shortened. The prognosis for people with these types of OI is quite variable, depending on the severity of the disorder and the number and severity of the fractures and bony deformities.

Fifty percent of all babies with OI Type II are stillborn. The rest of these babies usually die within a very short time after birth. In recent years, some people with Type II have lived into young adulthood.

Osteomyelitis

Definition

Osteomyelitis refers to a bone infection, almost always caused by a bacteria. Over time, the result can be destruction of the bone itself.

Description

Bone infections may occur at any age. Certain conditions increase the risk of developing such an infection, including sickle cell anemia, injury, the presence of a foreign body (such as a bullet or a screw placed to hold together a broken bone), intravenous drug use (such as heroin), diabetes, **kidney dialysis**, surgical procedures to bony areas, untreated infections of tissue near a bone (for example, extreme cases of untreated sinus infections have led to osteomyelitis of the bones of the skull).

Causes and symptoms

Staphylococcus aureus, a bacterium, is the most common organism involved in osteomyelitis. Other types of organisms include the mycobacterium which causes **tuberculosis**, a type of *Salmonella* bacteria in patients with sickle cell anemia, *Pseudomonas aeurginosa* in drug addicts, and organisms which usually reside in the gastrointestinal tract in the elderly. Extremely rarely, the viruses which cause **chickenpox** and **smallpox** have been found to cause a viral osteomyelitis.

There are two main ways that infecting bacteria find their way to bone, resulting in the development of osteomyelitis. These include:

- Spread via the bloodstream; 95% of these types of infections are due to *Staphylococcus aureus*. In this situation, the bacteria travels through the bloodstream to reach the bone. In children, the most likely site of infection is within one of the long bones, particularly the thigh bone (femur), one of the bones of the lower leg (tibia), or the bone of the upper arm (humerus). This is because in children these bones have particularly extensive blood circulation, making them more susceptible to invasion by bacteria. Different patterns of blood circulation in adults make the long bones less well-served by the circulatory system. These bones are therefore unlikely to develop osteomyelitis in adult patients. Instead, the bones of the spine (vertebrae) receive a lot of blood flow. Therefore, osteomyelitis in adults is most likely to affect a vertebra. Drug addicts may have osteomyelitis in the pubic bone or clavicle.
- Spread from adjacent infected soft tissue; about 50% of all such cases are infected by *Staphylococcus aureus*. This often occurs in cases where recent surgery or injury has resulted in a soft tissue infection. The bacteria can then spread to nearby bone, resulting in osteomyelitis. Patients with diabetes are particularly susceptible to this source of osteomyelitis. The diabetes interferes with both nerve sensation and good blood flow to the

feet. Diabetic patients are therefore prone to developing poorly healing wounds to their feet, which can then spread to bone, causing osteomyelitis.

Acute osteomyelitis refers to an infection which develops and peaks over a relatively short period of time. In children, acute osteomyelitis usually presents itself as **pain** in the affected bone, tenderness to pressure over the infected area, **fever** and chills. Patients who develop osteomyelitis, due to spread from a nearby area of soft tissue infection, may only note poor healing of the original wound or infection.

Adult patients with osteomyelitis of the spine usually have a longer period of dull, aching pain in the back, and no fever. Some patients note pain in the chest, abdomen, arm, or leg. This occurs when the inflammation in the spine causes pressure on a nerve root serving one of these other areas. The lower back is the most common location for osteomyelitis. When caused by tuberculosis, osteomyelitis usually affects the thoracic spine (that section of the spine running approximately from the base of the neck down to where the ribs stop).

When osteomyelitis is not properly treated, a chronic (long-term) type of infection may occur. In this case, the infection may wax and wane indefinitely, despite treatment during its active phases. An abnormal opening in the skin overlaying the area of bone infection (called a sinus tract) may occasionally drain pus. This type of smoldering infection may also result in areas of dead bone, called sequestra. These areas occur when the infection interferes with blood flow to a particular part of the bone. Such sequestra lack cells called osteocytes, which in normal bone are continuously involved in the process of producing bony material.

Diagnosis

Diagnosis of osteomyelitis involves several procedures. Blood is usually drawn and tested to demonstrate an increased number of the infection-fighting white blood cells (particularly elevated in children with acute osteomyelitis). Blood is also cultured in a laboratory, a process which allows any bacteria present to multiply. A specimen from the culture is then specially treated, and examined under a microscope to try to identify the causative bacteria.

Injection of certain radioactive elements into the bloodstream, followed by a series of x-ray pictures, called a scan (radionuclide scanning), will reveal areas of bone inflammation. Another type of scan used to diagnose osteomyelitis is called **magnetic resonance imaging**, or MRI

KEY TERMS

Abscess—A pus-filled pocket of infection.

Femur—The thighbone.

Humerus—The bone of the upper arm.

Thoracic—Pertaining to the area bounded by the rib cage.

Tibia—One of the two bones of the lower leg.

When pockets of pus are available, or overlaying soft tissue infection exists, these can serve as sources for samples which can be cultured to allow identification of bacteria present. A long, sharp needle can be used to obtain a specimen of bone (biopsy), which can then be tested to attempt to identify any bacteria present.

Treatment

Antibiotics are medications used to kill bacteria. These medications are usually given through a needle in a vein (intravenously) for at least part of the time. In children, these antibiotics can be given by mouth after initial treatment by vein. In adults, four to six weeks of intravenous antibiotic treatment is usually recommended, along with bed-rest for part or all of that time. Occasionally, a patient will have such extensive ostemyelitis that surgery will be required to drain any pockets of pus, and to clean the infected area.

Alternatives

General recommendations for the treatment of infections include increasing vitamin supplements, such as **vitamins** A and C. Liquid garlic extract is sometimes suggested. **Guided imagery** can help induce relaxation and improve pain, both of which are considered to improve healing. Herbs such as **echinacea** (*Echinacea* spp.), goldenseal (*Hydrastis canadensis*), Siberian **ginseng** (*Eleutherococcus senticosus*), and myrrh (*Commiphora molmol*) are all suggested for infections. Juice therapists recommend drinking combinations of carrot, celery, beet, and cantaloupe juices. A variety of homeopathic remedies may be helpful, especially those used to counter inflammation.

Prognosis

Prognosis varies depending on how quickly an infection is identified, and what other underlying conditions exist to complicate the infection. With quick, appropriate treatment, only about 5% of all cases of acute osteomyelitis will eventually become chronic

WWW.BOOKBAZ.IR

osteomyelitis. Patients with chronic osteomyelitis may require antibiotics periodically for the rest of their lives.

Prevention

About the only way to have any impact on the development of osteomyelitis involves excellent care of any **wounds** or injuries.

Osteopathic medicine *see* **Osteopathy**

Osteopathy

Definition

Osteopathy is a system and philosophy of healthcare that separated from traditional (allopathic) medical practice about a century ago. It places emphasis on the musculoskeletal system, hence the name—*osteo* refers to bone and *path* refers to disease. Osteopaths also believe strongly in the healing power of the body and do their best to facilitate that strength. During this century, the disciplines of osteopathy and allopathic medicine have been converging.

Purpose

Osteopathy shares many of the same goals as traditional medicine, but places greater emphasis on the relationship between the organs and the musculoskeletal system as well as on treating the whole individual rather than just the disease.

Precautions

Pain is the chief reason patients seek musculoskeletal treatment. Pain is a symptom, not a disease by itself. Of critical importance is first to determine the cause of the pain. Cancers, brain or spinal cord disease, and many other causes may be lying beneath this symptom. Once it is clear that the pain is originating in the musculoskeletal system, treatment that includes manipulation is appropriate.

Osteopathic physician demonstrating the articulation of a foot. *(Photo Researchers, Inc.)*

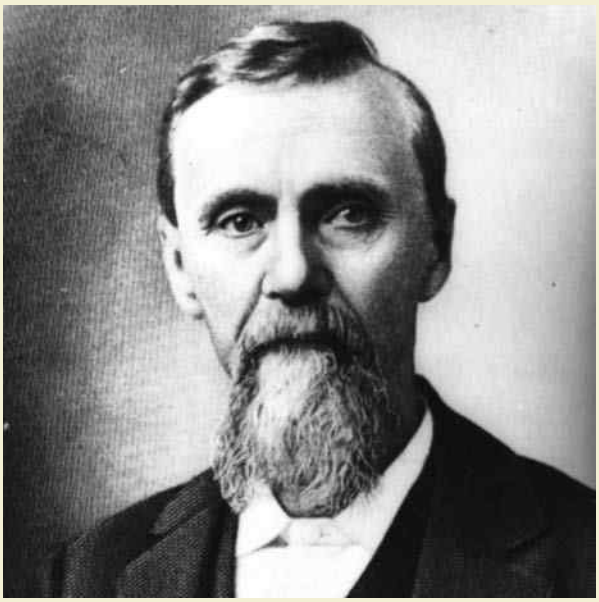
Description

History

Osteopathy was founded in the 1890s by Dr. Andrew Taylor, who believed that the musculoskeletal system was central to health. The primacy of the musculoskeletal system is also fundamental to **chiropractic**, a related health discipline. The original theory behind both approaches presumed that energy flowing through the nervous system is influenced by the supporting structure that encase and protect it—the skull and vertebral column. A defect in the musculoskeletal system was believed to alter the flow of this energy and cause disease. Correcting the defect cured the disease. Defects were thought to be misalignments—parts out of place by tiny distances. Treating misalignments became a matter of restoring the parts to their natural arrangement by adjusting them.

As medical science advanced, defining causes of disease and discovering cures, schools of osteopathy adopted modern science, incorporated it into their curriculum, and redefined their original theory of disease in light of these discoveries. Near the middle of the 20th century the equivalance of medical education between osteopathy and allopathic medicine was recognized,

ANDREW TAYLOR STILL (1828–1917)



Andrew Taylor Still. *(Corbis.)*

Andrew Taylor Still, the father of osteopathy, was born on August 6, 1828, in Virginia to Abram and Martha Still. Growing up on the frontier lands of Tennessee and Missouri provided the impetus for his first studies of the musculoskeletal system. Skinning squirrels and deer, Still became familiar with the relationship between bones, muscles, nerves, and veins long before he picked up an anatomy book. He later studied medicine under his doctor-preacher father and served as a Union surgeon during the Civil War.

Following the war, his distrust of traditional medicine grew when three of his children died of cerebrospinal meningitis. Still decided that the medications of his day were useless and that there had to be another way.

Still studied the attributes of good health so he could understand disease. He saw the body as a complex machine that, when working properly, stayed free of disease. He turned to a drugless, manipulative therapy believing disease was caused by a failure of the human machinery to carry the fluids necessary to maintain health. He called his holistic approach osteopathy for the Greek words *osteon,* meaning bone, and *pathos,* to suffer.

Still gained a following working as an itinerant healer, and in October 1892, he opened the American School of Osteopathy in Kirksville, Missouri. Still welcomed women even as other medical schools denied them access.

As of 2014, there are 30 osteopathic medicine colleges in the United States. The Kirksville College of Osteopathic Medicine remains open. More information on these types of programs can be found on http://aacom.org

and the DO degree (doctor of osteopathy) was granted official parity with the MD (doctor of medicine) degree. Physicians could adopt either set of initials.

However, osteopaths have continued their emphasis on the musculoskeletal system and their traditional focus on "whole person" medicine. Osteopaths constitute 5.5% of U.S. physicians, approximately 45,000. They provide 100 million patient visits a year. From its origins in the United States, osteopathy has spread to countries all over the world.

Practice

Osteopaths, chiropractors, and physical therapists are the experts in manipulations (adjustments). The place of manipulation in medical care is far from settled, but millions of patients find relief from it. Particularly backs, but also necks, command most of the attention of the musculoskeletal community. This community includes orthopedic surgeons, osteopaths, general and family physicians, orthopedic physicians, chiropractors, physical therapists, massage therapists, specialists in orthotics and **prosthetics**, and even some dentists and podiatrists. Many types of headaches also originate in the musculoskeletal system. Studies comparing different methods of treating musculoskeletal back, head, and neck pain have not reached a consensus, in spite of the huge numbers of people that suffer from it.

The theory behind manipulation focuses on joints, mostly those of the vertebrae and ribs. Some believe there is a very slight offset of the joint members—a subluxation. Others believe there is a vacuum lock of the joint surfaces, similar to two suction cups stuck together. Such a condition would squeeze joint lubricant out and produce abrasion of the joint surfaces with movement. Another theory focuses on weakness of the ligaments that support the joint, allowing it freedom to get into trouble. Everyone agrees that the result produces pain, that pain produces **muscle spasms and cramps**, which further aggravates the pain.

Some, but not all, practitioners in this field believe that the skull bones can also be manipulated. The skull is, in fact, several bones that are all moveable in infants. Whether they can be moved in adults is

WWW.BOOKBAZ.IR

KEY TERMS

Orthotics—Mechanical devices that assist function.

Prosthetics—Mechanical devices that replace missing body parts.

controversial. Other practitioners manipulate peripheral joints to relieve arthritis and similar afflictions.

Manipulation returns the joint to its normal configuration. There are several approaches. Techniques vary among practitioners more than between disciplines. Muscle relaxation of some degree is often required for the manipulation to be successful. This can be done with heat or medication. Muscles can also be induced to relax by gentle but persistent stretching. The manipulation is most often done by a short, fast motion called a thrust, precisely in the right direction. A satisfying "pop" is evidence of success. Others prefer steady force until relaxation permits movement.

Return of the joint to its normal status may be only the first step in treating these disorders. There is a reason for the initial event. It may be a fall, a stumble, or a mild impact, in which case the manipulation is a cure. On the other hand, there may be a postural misalignment (such as a short leg), a limp, or a stretched ligament that permits the joint to slip back into dysfunction. Tension, as well as pain, for emotional reasons causes muscles to tighten. If the pain has been present for any length of time, there will also be muscle deterioration. The osteopathic approach to the whole person takes all these factors into account in returning the patient to a state of health.

Other repairs may be needed. A short leg is thought by some to be a subluxation in the pelvis that may be manipulated back into position. Other short legs may require a lift in one shoe. Long-standing pain requires additional methods of **physical therapy** to rehabilitate muscles, correct posture, and extinguish habits that arose to compensate for the pain. Medications that relieve muscle spasm and pain are usually part of the treatment. Psychological problems may need attention and medication.

Risks

Manipulation has rarely caused problems. Once in a while too forceful a thrust has damaged structures in the neck and caused serious problems. The most common adverse event, though, is misdiagnosis. Cancers have been missed; surgical back disease has been ignored until spinal nerves have been permanently damaged.

Results

Many patients find that one or a series of manipulations cures long-standing pain. Other patients need repeated treatments. Some do not respond at all. It is always a good idea to reassess any treatment that is not producing the expected results.

Osteopetroses

Definition

Osteopetrosis (plural, osteopetroses) is a rare hereditary disorder that makes bones increase in both density (bone mass) and fragility and sometimes causes skeletal abnormalities. A potentially fatal condition that can deform bone structure and distort the appearance, osteopetrosis is also called chalk bones, ivory bones, or marble bones. Medically, it is also known as osteosclerosis fragilis generalisata and generalized congenital osteosclerosis. Albers-Schönberg disease is a mild type of the disorder.

Description

The disorder called osteopetrosis occurs when bones are spongy or porous, or new bone is repeatedly added to calcified cartilage (hardened connective tissue). Osteopetrosis is characterized by the failure of osteoclasts to resorb bone. An osteoclast is a type of bone cell that resorbs boney tissue, which is a necessary function for the healthy human skeleton.

The disorder may be inherited, either as a recessive or dominant trait. With osteopetrosis, bone density begins to increase at birth or earlier, but symptoms of the disorder may not become evident until adulthood. In mild cases, bone density increases at gradual,

This infant has osteopetrosis, a condition which thickens and hardens the bone. *(Custom Medical Stock Photo, Inc.)*

irregular intervals until full adult height is reached. Some bones are not affected. More severe osteopetrosis progresses at a rapid pace and destroys bone structure. This condition involves bones throughout the body, but the lower jaw is never affected.

Types of osteopetroses

There are several clinical types of osteopetrosis. These are based on age and clinical features. In early-onset osteopetrosis (also called malignant infantile osteopetrosis), the ends of the long bones of the arms and legs appear clubbed (widened and thickened) at birth, and bone density continues to increase sporadically or without pause. Early-onset osteopetroses can be a fatal condition, usually resulting in death before the age of two years.

Early-onset osteopetrosis is present at birth and is most often discovered by the time a baby is a few months old. It usually shortens the life expectancy of the affected baby. In fact, one-third of all cases result in death before the age of ten years. Intermediate osteopetrosis generally appears in children under the age of ten years. This condition, usually less severe than early-onset osteopetrosis, is not life-threatening.

Symptoms of adult, or delayed-onset, osteopetrosis (also called benign osteopetrosis) is a milder form when compared to the other two types and may not become evident until the child becomes a teenager or adult. There are two types of adult osteropetrosis. In type 1, the following occur:

- skull sclerosis (a hardening of body tissue) is apparent on the vault (the space in the skull within the neurocranium)
- scherosis is not noticeably visible on the spine or is only slightly visible
- endobones (bone within bone) are not present on the pelvis
- transverse banding of the metaphysis (wide portion of a long bone between the narrow part of the diaphysis and the epiphysis) is not present
- low risk of fracture exists
- normal values exist for serum acid phosphatase (a type of enzyme called phosphatase)

In type 2 adult osteropetroses, the following occur:

- skull sclerosis is apparent on the base
- scherosis is noticeably visible on the spine, with a "rugger-jersey" appearance (alternating dense-translucent-dense appearance, which looks like bands of a rugby jersey)
- endobones are present on the pelvis
- transverse banding of the metaphysis may or may not be present
- high risk of fracture exists
- very high values exist for serum acid phosphatase

About half of patients with adult osteopetroses may not have any symptoms (asymptomatic). Others may have **fractures**, bone pains, **osteomyelitis** (infection and inflammation of the bone or marrow), and various bony defects caused by the fragile condition of the bones. Repeat fracturing occurs in about 40% of patients.

Relatively common in many parts of the world, Albers-Schönberg disease is a mild form of this condition. People who have this disease are born with normal bone structure. Bone density increases as they age but does not affect appearance, health, intelligence, or life span.

Demographics

The German radiologist and gynecologist Heinrich Albers-Schönberg (1865–1921) is considered the first scientist to describe osteopetrosis, which he did in 1904. In the early part of the twenty-first century, an estimated one person in one hundred thousand to half a million is estimated to have the disease.

WWW.BOOKBAZ.IR

The World Health Organization (WHO) defined osteopetrosis as present when bone mineral density (BMD) is 2.5 standard deviations or more below the mean peak bone mass (which is the average determined from a population of young, healthy adults).

Causes and symptoms

Osteopetrosis is the result of a genetic defect that causes the body to add new bone more rapidly than existing bone disintegrates. Specifically, it is thought to be the result of malfunctioning osteoclasts (a type of bone cell that resorbs boney tissue).

When fibrous or bony tissue invades bone marrow and displaces red blood cells, the patient may develop anemia. Infection results when excess bone impairs the immune system, and hemorrhaging can occur when platelet production is disrupted. When the skeleton grows so thick that nerves are unable to pass between bones, the patient may have a **stroke** (sometimes causing facial **paralysis**) or become blind or deaf.

Symptoms associated with osteopetrosis include:

- bones that break easily and do not heal properly
- bruising
- convulsions
- enlargement of the liver, lymph glands, or spleen
- failure to thrive (delayed growth and development)
- hydrocephalus (fluid on the brain)
- macrocephaly (abnormal enlargement of the head)
- paralysis or loss of control of muscles in the face or eyes

Diagnosis

Osteopetrosis is usually diagnosed when x rays reveal abnormalities or increases in bone density. These scans may reveal that most bones are uniformly sclerotic, while others have alternating scierotic and lucent bands near the ends of long bones and in the wings of ilium (large expanded portion of the bone that laterally borders the greater pelvis). Bones may also appear club-like or have the appearance of being a bone within a bone (endobone). The skull may appear thicker than normal, especially at its base, while the sinuses are smaller than usual and the vertebrae are extraordinarily dense.

A **bone biopsy** can confirm the presence of osteopetrosis, but additional tests may be needed to distinguish one type of the disorder from another. Tests regularly performed for infantile osteopetrosis include:

KEY TERMS

Albers-Schönberg disease—The most common type of osteopetrosis; also called autosomal dominant osteopetrosis (ADO).

Bone marrow transplantation (BMT)—A procedure performed to replace damaged or destroyed bone marrow cells with healthy bone marrow stem cells.

Corticosteroid—A class of chemicals that are naturally produced in the adrenal cortex of vertebrates and artificially synthesized in laboratories.

Erythropoietin—A glycoprotein hormone that regulates the production of red blood cells.

- serum calcium
- parathyroid hormone (PTH)
- creatinine kinase isoform BB (CK-BB)

Tests for adult osteopetrosis include acid phosphatase, CK-BB, and serum bone-specific alkaline phosphatase.

Treatment

Osteopetrosis, along with other high bone density and mass disorders, is treated similarly to **osteoporosis** (a disorder involving low bone density and mass). For infantile osteopetrosis, high doses of **vitamin D** can stimulate cells responsible for disintegration of old bone and significantly reduce symptoms of severe disease. Diminished intake of **calcium** is often recommended along with the use of vitamin D. Gamma interferon therapy has been shown to reduce the risk of infection experienced by patients who are severely ill. This helps to improve the number and function of white blood cells, along with minimizing the risk of infection. In addition, **corticosteroids** are used to stimulate the resorption of bone and to reverse anemia. Prednisone is often used at a rate of one to two milligrams per kilogram per day. Further, erythropoietin (a glycoprotein hormone) is used to treat anemia.

For adult osteopetrosis, treatment is usually not necessary, although complications may require it.

When bone overgrowth deforms the shape of the skull, surgery may be required to relieve pressure on the brain. Orthodontic treatment is sometimes necessary to correct **malocclusion** (a condition that shifts the position of the teeth and makes closing the mouth

impossible). Professional counseling can help patients cope with the emotional aspects of deformed features.

Bone marrow transplants (BMT) have cured some cases of early-onset and malignant infantile osteopetrosis. Because from 30% to 60% of children who undergo BMT do not survive, this procedure is only selectively performed.

Prognosis

The severity of anemia seems to determine the course of an individual's osteopetrosis. When pronounced symptoms are present at the time of birth, the child's condition deteriorates rapidly. Death usually occurs within two years. When mild or moderate disease develops in older children or adults, and symptoms can be controlled, the patient is likely to survive. When left untreated at the time of birth, few children reach the age of ten years. However, when **bone marrow transplantation** (BMT) is used the prognosis is much better. If patients survive into adulthood, they have good long-term survival chances.

Prevention

Given that it is an inherited medical disorder, there is no known way to prevent osteopetroses.

Osteoporosis

Definition

Osteoporosis is a disease characterized by low bone mass and deterioration of bone tissues, leading to bone fragility and, consequently, an increase in fracture risk. The term osteoporosis comes from the Greek word *osteon*, meaning bone, and *porus*, meaning pore or passage. Osteoporosis literally makes bones porous. The amount of **calcium** stored in human bones decreases over time, causing the skeleton to weaken.

Demographics

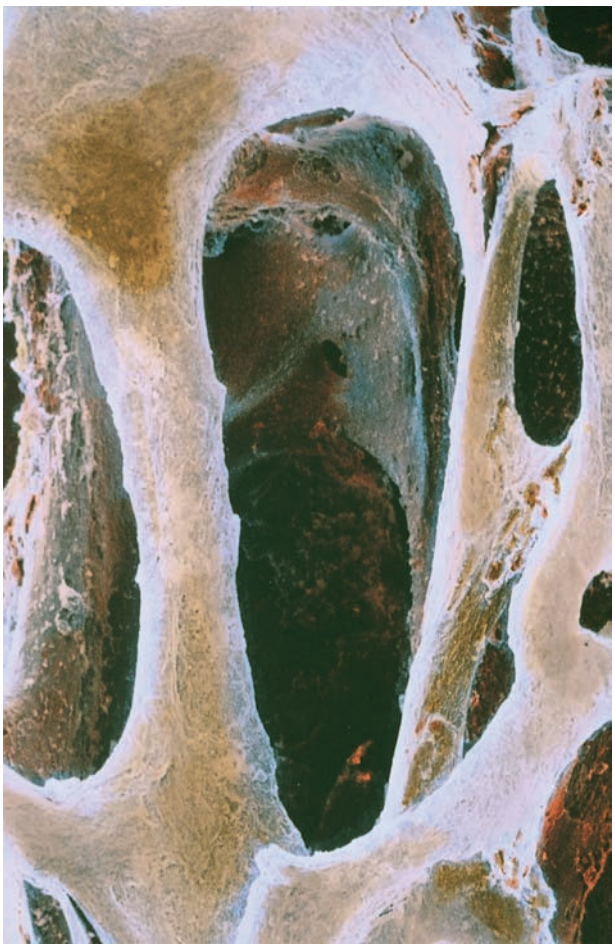
The National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) estimates that 10 million people (8 million women and 2 million men) in the United States have osteoporosis as of 2009, with another 34 million adults having low bone density, a condition called osteopenia. Osteopenia can develop into osteoporosis if it is not treated. Osteoporosis is responsible for more than 1.5 million **fractures** annually in the United States, including 300,000 hip fractures, 700,000 vertebral fractures, 250,000 wrist fractures, and more than 300,000 fractures in other parts of the body. The costs of treating osteoporosis and the fractures that it causes come to $14 billion each year. An osteoporosis-related fracture will occur in one in two women and one in eight men over the age of 50.

Although osteoporosis is often thought of as a woman's disease, it affects men, too. Men who take certain medications—particularly cortisone and other steroid drugs—have the same risk of developing osteoporosis as women who take these medications. Each year, 80,000 American men with osteoporosis will suffer a hip fracture, and one-third of them will die within a year.

Worldwide, osteoporosis is estimated to affect one in three women and one in 12 men over the age of 50. It is the most common metabolic bone disease in the world.

Osteoporosis in children is very unusual. There is a rare condition called juvenile idiopathic osteoporosis:

WWW.BOOKBAZ.IR



A scanning electron microscopy (SEM) image of cancellous (spongy) bone from an osteoporosis patient. Osteoporosis is characterized by increased brittleness of the bones and a greater risk of fractures. This is reflected here in the thin appearance of the bony network of the cancellous bone that forms the core of the body's long bones. *(Professor P. Motta/ Photo Researchers, Inc.)*

About 60 cases have been reported worldwide. The word idiopathic means that the cause of the condition is unknown.

Description

Osteoporosis is a disease that has no noticeable symptoms until the weakening of the bones leads to problems with posture, lower back **pain**, and brittle or easily broken bones. Although osteoporosis can appear at any age, it is most commonly a disease of adults. It develops when the wearing-out and removal of old bone—a process known as resorption—outpaces the production of new bone tissue.

Bone is living material. It is constantly broken down by cells called osteoclasts and built up again by cells called osteoblasts. This process is called bone remodeling, and it continues throughout an individual's life. Normally, more bone is built up than is broken down from birth through adolescence. In the late teens or early 20s, people reach their peak bone mass—the most bone that they will ever have. For 20 or so years, bone gain and bone loss remain approximately balanced in healthy people with good **nutrition**. However, when women enter **menopause**, usually in their mid to late forties, for the first five to seven years bone loss occurs at a rate of 1–5% a year. Men tend to lose less bone, and the loss often begins later in life. Osteoporosis occurs when bone loss continues and bones become so thin and their internal structure is so damaged that they break easily.

Bone remodeling occurs because bone is made primarily of calcium and phosphorous. Calcium is critically involved in muscle contraction, nerve impulse transmission, and many metabolic activities within cells. To remain healthy, the body must keep the level of free calcium ions (Ca^{2+}) within a very narrow concentration range. Besides providing a framework for the body, bone acts as a calcium "bank." When excess calcium is present in the blood, osteoblasts deposit it into bones where it is stored. When too little calcium is present, osteoblasts dissolve calcium from bones and move it into the blood. This process is controlled mainly by parathyroid hormone (PTH) secreted by the parathyroid glands in the neck. As people age, various conditions cause them to take more calcium out of the "bone bank" than they deposit, and osteoporosis (which literally means porous bones) eventually develops. A person's peak bone mass and the rate at which they lose it in later life affects their risk of developing osteoporosis; the higher the peak bone mass at age 30, the lower the risk of osteoporosis later on.

Doctors divide osteoporosis into three categories or types. Types 1 and 2 are considered primary because they are not caused by other diseases or conditions. Type 3 osteoporosis is sometimes called secondary osteoporosis because it results from taking certain drugs or having other diseases.

- Type 1: This type occurs in women after menopause and results from declining levels of estrogen and other sex hormones in the body. Sometimes called postmenopausal osteoporosis, it is the most common type of the disease. Type 1 may also occur in older men due to low levels of the sex hormone testosterone.
- Type 2: Sometimes called senile osteoporosis, this type of osteoporosis occurs in elderly men as well as elderly women because of decreased bone formation due to aging.
- Type 3: Type 3 osteoporosis is caused by long-term use of certain medications, particularly steroids and

drugs given to treat epilepsy; and by such conditions as malnutrition, Klinefelter syndrome, Turner syndrome, thyroid disorders, hemophilia, Marfan syndrome, rheumatoid arthritis, lupus, and lymphoma. Some studies indicate that people receiving chemotherapy for cancer are also at increased risk for this type of osteoporosis.

Risk factors

There are two basic categories of risk factors for osteoporosis. Some of these risk factors can be changed, while others cannot be altered. Risk factors that cannot be changed include:

- Sex. Women have four times the risk of the disease as men, particularly after the menopause.
- Race/ethnicity. Asian and Caucasian women have a higher risk of osteoporosis than African American or Hispanic women. Although their risk is smaller, African-American and Hispanic-American women should still take precautions against osteoporosis. An estimated 10% of African-American women over age 50 have osteoporosis and an additional 30% have low bone density that puts them at risk of developing osteoporosis.
- Body build. Small-boned people of either sex are at greater risk of osteoporosis than people with average or heavy bones.
- Age. Both men and women have an increased risk of osteoporosis as they get older. The highest incidence of the disease is found among those men and women aged 80 or older.
- Genetic factors. A tendency for bones to fracture easily is thought to run in some families.

Risk factors for osteoporosis that people can change include:

- Low sex hormone levels. These can be raised in both men and women by hormone replacement therapy.
- Eating disorders, particularly anorexia.
- Depression. Emotional depression can be treated, most often with a combination of medication and psychotherapy.
- Low intake of calcium and vitamin D. People can change their eating habits and take vitamin or calcium supplements.
- Smoking and alcohol intake. People can quit smoking and drink in moderation.
- Getting the right amount of exercise. Bed rest or inadequate exercise can weaken bones, but so can too much exercise (such as marathon running).
- Medications. People who are taking medications that increase their risk of osteoporosis can ask their doctor about alternatives.

Certain diseases also increase a person's risk of developing osteoporosis:

- hyperthyroidism
- hyperparathyroidism
- celiac disease
- inflammatory bowel disease (IBD)
- cystic fibrosis
- diabetes
- chronic liver disease

Causes and symptoms

The basic cause of osteoporosis is that the loss of bone tissue occurs faster than the production of replacement bone. The increased rate of bone loss can be particularly critical if the person had a low or inadequate peak bone mass to begin with. A low peak bone mass can result from **malnutrition** in childhood; inadequate intake of calcium or **vitamin D** (necessary for the body to make use of calcium in the diet); an eating disorder in adolescence, when the body's need for calcium is at its height; or not getting enough **exercise**.

Genetic profile

Osteoporosis results from a complex interaction between genetic and environmental factors throughout life. Evidence suggests that peak bone mass is inherited, but current genetic markers are able to explain only a small proportion of the variation in individual bone mass or fracture risk. As of 2014, no specific mode of inheritance has been identified. Heritability of bone mass has been estimated to account for 60–90% of its variance. Studies have shown reduced bone mass in daughters of osteoporotic women when compared with controls; in men and women who have first-degree relatives with osteoporosis; and in perimenopausal women who have a family history of hip fracture. Body weight in infancy may be a determinant of adult bone mineral area.

Some scientists think that environmental influences during early life interact with the genome to establish the functional level of a variety of metabolic processes involved in skeletal growth.

Many candidate genes exist for osteoporosis, however relatively few have been studied. The first candidate gene to be identified was the vitamin D receptor (VDR) gene, and studies are ongoing as to how much this gene accounts for variance in bone mass. The response of bone mass to dietary supplementation with vitamin D and calcium is known to be dependent, in part, on VDR polymorphisms. Other genes may aid in establishing who would benefit from

WWW.BOOKBAZ.IR

KEY TERMS

Alendronate—A non-hormonal drug used to treat osteoporosis in postmenopausal women.

Bisphosphonates—Compounds that slow bone loss and increase bone density.

Calcitonin—A naturally occurring hormone made by the thyroid gland that can be used as a drug to treat osteoporosis and Paget's disease of the bone.

Compression fracture—A fracture caused by the collapse of a vertebra in the spinal column, usually caused either by trauma or by weakening of the bone in osteoporosis.

Fragility fracture—A fracture that occurs as a result of a fall from standing height or less. A person with healthy bones would not suffer a broken bone falling from a standing position.

Glucocorticoids—A general class of adrenal cortical hormones that are mainly active in protecting against stress and in protein and carbohydrate metabolism. They are widely used in medicine as anti-inflammatories and immunosuppresives.

Kyphosis—The medical term for curvature of the upper spine. Osteoporosis is a common cause of kyphosis in older adults.

Osteoblast—A type of bone cell that is responsible for bone formation. The number of osteoblasts in a person's body decreases with age.

Osteoclast—A type of bone cell that removes bone tissue.

Osteopenia—The medical name for low bone mass, a condition that often precedes osteoporosis.

Polymorphism—A change in the base pair sequence of DNA that may or may not be associated with a disease.

Resorption—The removal of old bone from the body.

Selective estrogen receptor modulator—A hormonal preparation that offers the beneficial effects of hormone replacement therapy (HRT) without the increased risk of breast and uterine cancer associated with HRT.

T-score—The score on a bone densitometry test, calculated by comparing the patient's bone mineral density to that of a healthy 30-year-old of the same sex and race.

Vertebra (plural, vertebrae)—One of the segments of bone that make up the spinal column.

treatments like **hormone replacement therapy**, bisphosophonates, or exercise. Associations between bone mass and polymorphisms have also been found in the estrogen receptor gene, the interleukin-6 genes, the transforming growth factor beta, and a binding site of the collagen type I alpha1 (COLIA1) gene.

The risk of osteoporosis is greatly determined by peak bone mass, and any gene linked to fractures in the elderly may possibly be associated with low bone mass in children as well.

Symptoms

Osteoporosis can proceed for a long time without any noticeable symptoms. Some older adults simply notice that their height is shrinking. This loss of height is caused by compression of the bones in the spinal column. Sometimes the vertebrae fracture as they come closer together; this type of injury is called a compression fracture and may produce noticeable back pain.

Over many years, a sequence of spinal compression fractures may cause **kyphosis**, the bent-over posture known as dowager's or widow's hump. These fractures rarely require surgery, and they can range from causing minor discomfort to severe painful episodes of backache. In either case, pain generally subsides gradually over one to two months.

Another common symptom of osteoporosis is a fragility fracture. Fragility fractures occur when a person falls from their standing position or a lower height and breaks a bone that would not break in a person with healthy bone. The most common locations of fragility fractures in people with osteoporosis are the wrists, the hips, and the vertebrae in the spine. The patient may experience the pain in various ways; some describe it as sharp while others describe it as dull or nagging. In some cases the pain gets worse when the patient is trying to walk or move around.

Diagnosis

Since osteoporosis can develop undetected for decades until a fracture occurs, early diagnosis is important. Osteoporosis is most likely to be diagnosed following a fragility fracture. The doctor will take a careful history of the patient's risk factors, including a possible family history of easily broken bones as well

as a medication history and questions about such lifestyle factors as exercise, diet, **smoking**, and drinking.

Examination

The **physical examination** should include measurement of the patient's height, evaluation of possible loss of height, and assessment for evidence of kyphosis.

Tests

The doctor may order a blood test to rule out a thyroid disorder or to check the levels of sex hormones in the patient's blood.

A bone mineral density test (BMD) is the only way to diagnose osteoporosis and determine risk for future fracture. The painless, noninvasive test measures bone density and helps determine whether medication is needed to help maintain bone mass, prevent further bone loss, and reduce fracture risk. To take this test, the patient lies on an examination table while two x-ray beams of different intensities are aimed at the bones. The result is called a T-score. It is calculated by comparing the patient's bone mineral density to that of a healthy 30-year-old of the same sex and race. A T-score of -1.0 or higher is normal; a score between -1.0 and -2.5 indicates osteopenia; a score below -2.5 indicates osteoporosis.

Several different machines measure bone density. Central machines, such as the dual energy x-ray absorptiometry (DXA or DEXA) and quantitative computed tomography (QCT), measure density in the hip, spine and total body. Peripheral machines, such as radiographic absorptiometry (RA), peripheral dual energy x-ray absorptiometry (pDXA), and peripheral quantitative computed tomography (pQCT), measure density in the finger, wrist, kneecap, shin bone, and heel.

A physician may be able to observe osteoporotic bone in a routine spinal x ray, however, BMD tests are more accurate and can measure small percentages of lost bone density. In an x ray, osteoporotic bone appears less dense and the image is less distinct, suggesting weaker bone.

As of 2014, the U.S. Preventive Services Task Force recommends using dual energy x-ray absorptiometry to screen all women 65 years and older and women 60 to 64 years of age who have increased fracture risk. Some physicians also recommend bone density testing at menopause at whatever age it occurs to begin preventive treatment if necessary. The major risk factors are low body weight, low calcium intake, poor health, and a history of osteoporosis in the family.

Some healthcare organizations recommend considering screening in all men 70 years and older, as well as for men with one of the following risk factors: bone fracture, poor health, or **low testosterone** levels.

Treatment

DRUGS. Medications are an important part of treatment for osteoporosis. Various drugs have been shown to be effective in preventing or slowing bone loss and increasing bone mass. These include:

- *Hormone replacement therapy*. For women with postmenopausal osteoporosis, estrogen replacement therapy helps halt bone loss and exerts a modest bone-building effect. Stopping hormone therapy restarts bone loss, so long-term treatment is usually recommended. HRT used to be considered the mainstay of treating osteoporosis in women. But with newer studies indicating that HRT increases the risk of heart disease and cancer in some women, other medications that work by slowing the process of bone loss or by increasing bone density over time are more widely prescribed as of 2014. Some of these medications have the additional advantage of working well in men with osteoporosis and in people who must take steroid drugs for other health problems.
- *Raloxifene*. One of a class of drugs called selective estrogen receptor modulators (SERMs) that appear to prevent bone loss, raloxifene (Evista) produces small increases in bone mass. It is approved for the prevention and treatment of osteoporosis. Like estrogens, SERMs produce changes in blood lipids that may protect against heart disease, although the effects are not as potent as that of estrogen. Unlike estrogens, SERMs do not appear to stimulate uterine or breast tissue.
- *Alendronate*. One of a class of medications called bisphosphonates, alendronate (Fosamax) may prevent bone loss, increase bone mass, and reduce the risk of fractures. Patients receiving any bisphosphonate, however, should take calcium and vitamin D before and during treatment with a bisphosphonate to lower the risk of side effects from these drugs.
- *Risedronate*. Also from the bisphosphonate family, risedronate (Actonel) has been shown to reduce bone loss, increase bone density, and reduce the risk of fractures.
- *Calcitonin*. A hormone that regulates calcium levels in the blood, calcitonin may prevent bone loss. It is approved for treatment of diagnosed osteoporosis.

WWW.BOOKBAZ.IR

Lifestyle changes

Recommended lifestyle changes that can reduce the rate of bone loss include regular exercise, particularly weight-bearing forms of exercise like walking, dancing, treadmill exercises, and jumping. Other measures include quitting smoking, taking supplemental vitamin D and calcium, and watching one's alcohol intake.

Surgery

Unfortunately, surgical treatment for osteoporosis is often necessary. It is usually tied to fractures that result from advanced stages of the disease. For complicated fractures, such as broken hips, hospitalization and a surgical procedure are required. In **hip replacement** surgery, the broken hip is removed and replaced with a new hip made of plastic, or metal and plastic. Though the surgery itself is usually successful, complications of the hip fracture can be serious. Those individuals have a 5–20% greater risk of dying within the first year following that injury than do others in their age group. A large percentage of those who survive are unable to return to their previous level of activity, and many end up moving from self-care to a supervised living situation or nursing home. Getting early treatment and taking steps to reduce bone loss are vital.

Alternatives

Alternative treatments for osteoporosis focus on maintaining or building strong bones. They include nutritional and herbal therapies and homeopathy.

NUTRITIONAL THERAPY. A healthful diet low in fats and animal products and containing whole grains, fresh fruits and vegetables, and calcium-rich foods (such as dairy products, dark-green leafy vegetables, sardines, salmon, and almonds), along with **nutritional supplements** (such as calcium, magnesium, and vitamin D) are important components of nutritional approaches to treating this disease.

Women should also eat more soy products such as tofu, soy burgers, other soy-based products, or miso. Soy beans contain a substance called isoflavones which have estrogen-like activity. Isoflavones may help to increase bone density, alleviate hot flashes and other menopausal symptoms, lower the risk of cancer, and even reduce the risk of heart attacks. Natural hormone therapy, such as the use of soy products, is a safer alternative to synthetic estrogenic hormones, which may increase the risk of **breast cancer**.

In addition, women should avoid foods that may accelerate bone loss. They should avoid having too much salt in their diet, not only because salt raises the blood pressure but also because it may contribute to osteoporosis. They should also cut down on coffee, caffeinated sodas, and alcohol. High consumption of these beverages, studies have shown, are associated with accelerated drop in bone density and increase risk of bone fracture in old age. Caffeinated sodas are especially bad for the bones because in addition to containing **caffeine**, they have high amounts of phosphoric acid. Phosphoric acid increases bone resorption, thus decreasing bone density.

HERBAL SUPPLEMENTS. Herbal supplements for osteoporosis emphasize such calcium-containing plants as horsetail (*Equisetum arvense*), oat straw (*Avena sativa*), alfalfa (*Medicago sativa*), licorice (*Glycyrrhiza glabra*), marsh mallow (*Althaea officinalis*), and sourdock (*Rumex crispus*). There are, however, few data from clinical trials to support the use of these herbs.

HOMEOPATHY. Homeopathic remedies for osteoporosis focus on treatments believed to help the body absorb calcium. These remedies may include such substances as *Calcarea carbonica* (calcium carbonate) or *Silica* (flint). Again, there are few data other than isolated case reports regarding the effectiveness of these remedies.

Prognosis

The prognosis for osteoporosis depends on its type and cause; the patient's age, sex, and ethnicity; the presence of other diseases or disorders; and the patient's willingness to follow the doctor's recommendations about medications and lifestyle changes.

People do not die from osteoporosis itself but from complications from bone fractures. These complications can include chronic pain, **pneumonia**, **blood clots** in the deep veins of the leg, or breathing disorders caused by the stooped posture resulting from compression fractures in the spine. The death rate within the first six months after a hip fracture is 14%. Even patients who survive often have a greatly lowered quality of life.

Osteoporosis is likely to continue to be a serious health concern because of the **aging** of the American population. As people continue to live longer, the number of people with Type 2 (age-related) osteoporosis will increase. In addition, people who are at risk for osteoporosis because of sex, race, or a family history of weak bones may not be completely able to prevent the disease even by careful attention to diet and exercise. It is possible that more effective medications to prevent bone loss or restore bone density will be developed.

Prevention

People cannot change such risk factors for osteoporosis as age, sex, and race, but they can eat properly, exercise regularly, and ask their doctor about vitamin D and calcium supplements. Male as well as female adolescents should participate in sports and get adequate calcium in the diet in order to build up a high peak bone mass before midlife. Women who have not yet gone through menopause should get at least 1,000 milligrams (mg) of elemental calcium and a minimum of 800 international units (IU) of vitamin D every day; women who have completed menopause, anyone who must take steroid medications, and all men and women over 65 should aim for 1,500 mg of elemental calcium and at least 800 IU of vitamin D daily.

Other recommendations for lowering the risk of osteoporosis in older adults include:

- Participate in regular weight-bearing exercise, such as walking, jogging, tennis, weight-lifting, and cross-county skiing to strengthen bones.
- Stop smoking.
- Reduce intake of caffeine to not more than three cups a day.
- Limit alcohol intake to not more than two drinks per day.
- Avoid excessive amounts of dietary fiber as it binds to calcium and may interfere with absorption.

Older adults should also try to reduce their risk of falls whether or not they have osteoporosis. There are balance and strength exercises that older adults can practice at home. In addition, such safety measures as wearing properly fitted shoes with non-slip soles, checking one's house for loose rugs, poor lighting, and other hazards, installing grab bars in shower stalls, and keeping a cordless phone within easy reach in case of an accident are all good forms of fall prevention.

Nutrition/Dietetic concerns

Calcium and vitamin D are both essential to building and maintaining strong bones. Dairy products are a good source of these nutrients. Calcium supplements are recommended for many women who have difficulty getting enough calcium in their diet. Recommended dietary allowances (RDAs) and lists of foods that are high in calcium and vitamin D can be found in their individual entries. Fluoride also is needed to develop healthy bones and teeth.

Young people with the eating disorder **anorexia nervosa** are at especially high risk of developing osteoporosis later in life because they have poor, unbalanced **diets**. The menstrual cycle in girls with anorexia is often delayed in starting or if it has started, stops. In addition, people with anorexia almost never get enough calcium to build strong bones during adolescence and they make unusually larger amounts of cortisol, a corticosteroid made by the adrenal gland that causes bone loss. Although the effect of this eating disorder on bones will not be seen until the individual is older, failure to build strong, dense bones during the teen years substantially increases the risk of osteoporosis later.

Healthcare team roles

Doctors, nurses, physical therapists, radiation technologists, and dietitians all play roles in the process of controlling osteoporosis. Because osteoporosis is treatable but not curable, the main responsibility for controlling the progress of the disease rests with the patient. All of these team members play an important role in identifying risk of osteoporosis before it strikes and in convincing the patient to take appropriate steps (including lifestyle modification) to minimize the dangers of fracturing major bones.

Caregiver concerns

A survey conducted by the International Osteoporosis Foundation (IOF) in 11 countries showed widespread denial of personal risk by postmenopausal women, lack of discussion about osteoporosis with their primary care physician, and restricted access to diagnosis and treatment before occurrence of the first fracture. The unfortunate result is that osteoporosis is too often underdiagnosed and undertreated in this population group.

Ostomy

Definition

A surgical procedure creating an opening in the body for the discharge of body wastes.

Purpose

Certain diseases of the bowel or urinary tract involve removing all or part of the intestine or bladder. This creates a need for an alternate way for feces or urine to leave the body. To fill that need, an opening is surgically created in the abdomen for body wastes to pass through. The surgical procedure is called an ostomy. The opening that is created at the end of the bowel or ureter is called a stoma, which is pulled through the abdominal wall.

Description

Different types of ostomy are performed depending on how much and what part of the intestines or bladder is removed.

The three most common types of ostomies are:

- colostomy
- ileostomy
- urostomy

Colostomy

A **colostomy** is a when a small portion of the colon (large intestine) is brought to the surface of the abdominal wall to allow stool to be eliminated. A colostomy may be temporary or permanent. A permanent colostomy usually involves the loss of the rectum.

A colostomy might be performed due to cancer, **diverticulitis**, imperforate anus, Hirschsprung's disease, or **trauma** to the affected area.

Ileostomy

An ileostomy is an opening created in the small intestine to bypass the colon for stool elimination. The end of the ileum, which is the lowest part of the small intestine, is brought through the abdominal wall to form a stoma.

Ileoanal reservoir surgery is an alternative to a permanent ileostomy. It requires two surgical procedures. The first removes the colon and rectum, and creates a temporary ileostomy. The second procedure creates an internal pouch from a portion of the small intestine to hold stool. This is then attached to the anus. Since the muscle of the rectum is left in place, there is control over bowel movements.

An ileostomy might be performed due to ulcerative **colitis**, Crohn's disease, or **familial polyposis**.

Urostomy

A urostomy is a surgical procedure that diverts urine away from a diseased or defective bladder. Among several methods to create the urostomy, the most common method is called an ileal or cecal conduit. Either a section at the end of the small intestine (ileum) or at the beginning of the large intestine (cecum) is relocated surgically to form a stoma for urine to pass out of the body. Other common names for this procedure are ileal loop or colon conduit.

A urostomy may be performed due to **bladder cancer**, spinal cord injuries, malfunction of the bladder, and **birth defects** such as **spina bifida**.

Since colostomy, ileostomy, and usotomy bypass the sphincter muscle, the patient has no voluntary control over bowel movements and must wear an external pouch to catch the discharge.

KEY TERMS

Crohn's disease—A chronic inflammatory disease, primarily involving the small and large intestine, but which can affect other parts of the digestive system as well.

Diverticulitis—Inflammation of the diverticula (small outpouchings) along the wall of the colon, the large intestine.

Familial polyposis—An inherited condition in which several hundred polyps develop in the colon and rectum.

Hirschsprung disease—Hirschsprung disease is a congenital abnormality (birth defect) of the bowel in which there is absence of the ganglia (nerves) in the wall of the bowel. Nerves are missing starting at the anus and extending a variable distance up the bowel. This results in megacolon (massive enlargement of the bowel) above the point where the nerves are missing. (The nerves are needed to assist in the natural movement of the muscles in the lining of the bowels that move bowel contents through.)

Ileum—The lowest part of the small intestine, located beyond the duodenum and jejunum, just before the large intestine (the colon).

Imperforate anus—A congenital malformation (a birth defect) in which the rectum is a blind alley (a cul-de-sac) and there is no anus.

Spina bifida—A birth defect (a congenital malformation) in which there is a bony defect in the vertebral column so that part of the spinal cord, which is normally protected within the vertebral column, is exposed. People with spina bifida can suffer from bladder and bowel incontinence, cognitive (learning) problems and limited mobility.

Preparation

Aftercare

The skin around the stoma, called the peristomal skin, must be protected from direct contact with discharge. The discharge can be irritating to the stoma since it is very high in digestive enzymes. The peristomal skin should be cleansed with plain soap and rinsed with water at each change of the pouch.

The stoma can change in size due to weight gain/loss or several other situations. To ensure proper fit of discharge pouch the stoma should be measured each time supplies are purchased.

Results

Most ostomy pouches are inconspicuous and can be worn under almost any kind of clothing. There are typically no restrictions of activity, sport, or travel with an ostomy. Certain contact sports would warrant special protection for the stoma.

After recovery from surgery, most people with ostomies can resume a balanced diet.

Ostomy surgery does not generally interfere with a person's sexual or reproductive capacities.

Abnormal results

After an ileostomy, water and electrolyte loss may occur. It may be necessary to drink a significant amount of fluid or fruit juice each day to prevent **dehydration**.

WWW.BOOKBAZ.IR

After any type of ostomy surgery digestion and absorbtion of medications may also be affected.

High-fiber foods can cause blockages in the ileum, especially after surgery. Chewing food well helps break fiber into smaller pieces and makes it less likely to accumulate at a narrow point in the bowel. Drinking plenty of fluids can also help.

Risks

People with ostomies can be prone to certain types of skin infections. Skin irritations or **rashes** around the stoma may be caused by leakage from around the pouch due to an improperly fitted pouch. Correctly fitting the pouch and carefully cleaning the skin around the stoma after each change are the best ways of preventing skin irritation.

Urinary tract infections are common among people who have urostomies. Preventative measures include drinking plenty of fluids, emptying the pouch regularly and using a pouch with an anti-reflux valve to prohibit the discharge from moving back into the stoma.

Otitis externa

Definition

Otitis externa refers to an infection of the ear canal, the tube leading from the outside opening of the ear in towards the ear drum.

A close-up image of the ear of an elderly man suffering from non-infectious otitis externa. The skin in the ear canal and outer ear is scaly. *(Custom Medical Stock Photo, Inc.)*

Description

The external ear canal is a tube approximately 1 in (2.5 cm) in length. It runs from the outside opening of the ear to the start of the middle ear, designated by the ear drum or tympanic membrane. The canal is partly cartilage and partly bone. In early childhood, the first two-thirds of the canal is made of cartilage, and the last one-third is made of bone. By late childhood, and lasting throughout all of adulthood, this proportion is reversed, so that the first one-third is cartilage, and the last two-thirds is bone. The lining of the ear canal is skin, which is attached directly to the covering of the bone. Glands within the skin of the canal produce a waxy substance called cerumen (popularly called earwax). Cerumen is designed to protect the ear canal, repel water, and keep the ear canal too acidic to allow bacteria to grow.

Causes and symptoms

Bacteria, fungi, and viruses have all been implicated in causing ear infections called otitis externa. The most common cause of otitis externa is bacterial infection. The usual offenders include *Pseudomonas aeruginosa*, *Enterobacter aerogenes*, *Proteus mirabilis*, *Klebsiella pneumoniae*, *Staphylococcus epidermidis*, and bacteria of the family called Streptococci. Occasionally, fungi may cause otitis externa. These include *Candida* and *Aspergillus*. Two types of viruses, called herpesvirus hominis and varicella-zoster virus, have also been identified as causing otitis externa.

Otitis externa occurs most often in the summer months, when people are frequenting swimming pools and lakes. Continually exposing the ear canal to moisture may cause significant loss of cerumen. The delicate skin of the ear canal, unprotected by cerumen, retains moisture and becomes irritated. Without cerumen, the ear canal stops being appropriately acidic, which allows bacteria the opportunity to multiply. Thus, the warm, moist, dark environment of the ear canal becomes a breeding ground for bacteria.

Other conditions predisposing to otitis externa include the use of cotton swabs to clean the ear canals. This pushes cerumen and normal skin debris back into the ear canal, instead of allowing the ear canal's normal cleaning mechanism to work, which would ordinarily move accumulations of cerumen and debris out of the ear. Also, putting other items into the ear can scratch the canal, making it more susceptible to infection.

The first symptom of otitis externa is often **itching** of the ear canal. Eventually, the ear begins to feel extremely painful. Any touch, movement, or pressure on the outside structure of the ear (auricle) may cause quite severe **pain**. This is because of the way in which the skin lining the ear canal is directly attached to the covering of the underlying bone. If the canal is sufficiently swollen, hearing may become muffled. The canal may appear swollen and red, and there may be evidence of greenish-yellow pus.

In severe cases, otitis externa may have an accompanying **fever**. Often, this indicates that the outside ear structure (auricle) has become infected as well. It will become red and swollen, and there may be enlarged and tender lymph nodes in front of, or behind, the auricle.

A serious and life-threatening otitis externa is called malignant otitis externa. This is an infection which most commonly affects patients who have diabetes, especially the elderly. It can also occur in other patients who have weakened immune systems. In malignant otitis externa, a patient has usually had minor symptoms of otitis externa for some months, with pain and drainage. The causative bacteria is usually *Pseudomonas aeruginosa*. In malignant otitis externa, this bacteria spreads from the external canal into all of the nearby tissues, including the bones of the skull. Swelling and destruction of these tissues may lead to damage of certain nerves, resulting in spasms of the jaw muscles or **paralysis** of the facial muscles. Other, more severe, complications of this very destructive infection include **meningitis** (swelling and infection of the coverings of the spinal cord and brain), brain infection, or **brain abscess** (the development of a pocket of infection with pus).

Diagnosis

Diagnosis of uncomplicated otitis externa is usually quite simple. The symptoms alone, of ear pain worsened by any touch to the auricle, are characteristic of otitis externa. Attempts to examine the ear canal will usually reveal redness and swelling. It may be impossible (due to pain and swelling) to see much of the ear canal, but this inability itself is diagnostic.

If there is any confusion about the types of organisms causing otitis externa, the canal can be gently swabbed to obtain a specimen. The organisms present in the specimen can then be cultured (allowed to multiply) in a laboratory, and then viewed under a microscope to allow identification of the causative organisms.

If the rare disease malignant otitis externa is suspected, computed tomography scan (CT scan) or **magnetic resonance imaging** (MRI) scans will be performed to determine how widely the infection has spread within bone and tissue. A swab of the external canal will not necessarily reveal the actual causative organism, so some other tissue sample (biopsy) will need to be obtained. The CT or MRI will help the practitioner decide where the most severe focus of infection is located, in order to guide the choice of a biopsy site.

Treatment

Antibiotics which can be applied directly to the skin of the ear canal (**topical antibiotics**) are usually excellent for treatment of otitis externa. These are often combined in a preparation which includes a steroid medication. The steroid helps cut down on the inflammation and swelling within the ear canal. Some practitioners prefer to insert a cotton wick into the ear canal, leaving it there for about 48 hours. The medications are applied directly to the wick, enough

WWW.BOOKBAZ.IR

KEY TERMS

Auricle—The external structure of the ear.

Biopsy—The removal and examination, usually under a microscope, of tissue from the living body. Biopsy is used for diagnosis.

Cerumen—Earwax.

times per day to allow the wick to remain continuously saturated. After the wick is removed, the medications are then put directly into the ear canal three to four times each day.

In malignant otitis externa, antibiotics will almost always need to be given through a needle in the vein (intravenously or IV). If the CT or MRI scan reveals that the infection has spread extensively, these IV antibiotics will need to be continued for six to eight weeks. If the infection is in an earlier stage, two weeks of IV antibiotics can be followed by six weeks of antibiotics by mouth.

Prognosis

The prognosis is excellent for otitis externa. It is usually easily treated, although it may tend to recur in certain susceptible individuals. Left untreated, malignant otitis externa may spread sufficiently to cause death.

Prevention

Keeping the ear dry is an important aspect of prevention of otitis externa. Several drops of a mixture of alcohol and acetic acid can be put into the ear canal after swimming to insure that it dries adequately.

The most serious complications of malignant otitis externa can be avoided by careful attention to early symptoms of ear pain and drainage from the ear canal. Patients with conditions that put them at higher risk for this infection (diabetes, conditions which weakened the immune system) should always report new symptoms immediately.

Otitis media

Definition

Otitis media is an infection of the middle ear space, behind the eardrum (tympanic membrane). It is characterized by **pain**, **dizziness**, and partial loss of hearing.

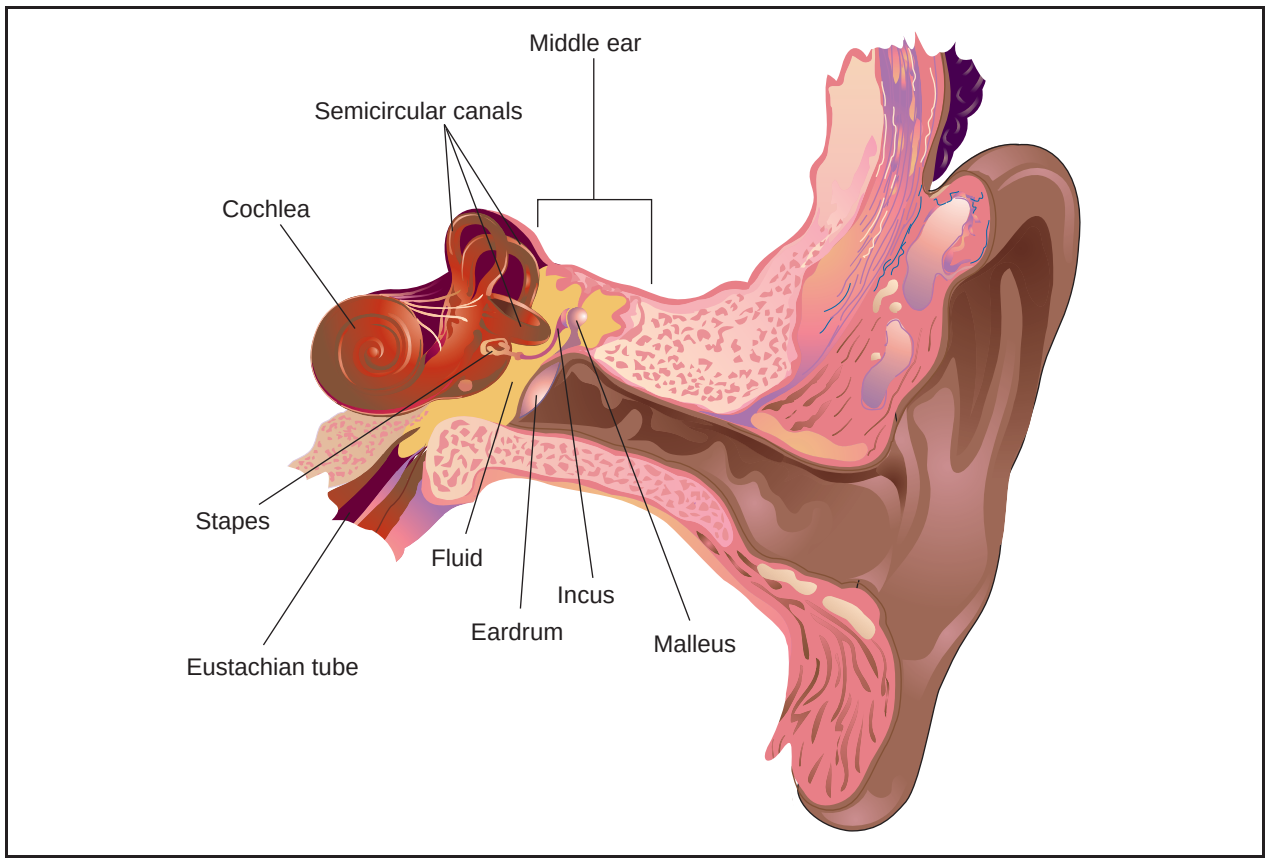
Description

A little knowledge of the basic anatomy of the middle ear will be helpful for understanding the development of otitis media. The external ear canal is that tube which leads from the outside opening of the ear to the structure called the tympanic membrane. Behind the tympanic membrane is the space called the middle ear. Within the middle ear are three tiny bones, called ossicles. Sound (in the form of vibration) causes movement in the eardrum, and then the ossicles. The ossicles transmit the sound to a structure within the inner ear, which sends it to the brain for processing.

The nasopharynx is that passageway behind the nose which takes inhaled air into the breathing tubes leading to the lungs. The eustachian tube is a canal which runs between the middle ear and the nasopharynx. One of the functions of the eustachian tube is to keep the air pressure in the middle ear equal to that outside. This allows the eardrum and ossicles to vibrate appropriately, so that hearing is normal.

By age three, almost 85% of all children will have had otitis media at least once. Babies and children between the ages of six months and six years are most likely to develop otitis media. Children at higher risk factors for otitis media include boys, children from poor families, Native Americans, Native Alaskans, children born with **cleft palate** or other defects of the structures of the head and face, and children with **Down syndrome**. Exposure to cigarette smoke significantly increases the risk of otitis media as well as other problems affecting the respiratory system. Also, children who enter daycare at an early age have more upper respiratory infections (URIs or colds), and thus more cases of otitis media. The most usual times of year for otitis media to strike are in winter and early spring (the same times URIs are most common).

Otitis media is an important problem, because it often results in fluid accumulation within the middle ear (effusion). The effusion can last for weeks to months. Effusion within the middle ear can cause significant hearing impairment. When such hearing impairment occurs in a young child, it may interfere with the development of normal speech.



Otitis media is an ear infection in which fluid accumulates within the middle ear. A common condition occurring in childhood, it is estimated that 85% of all U.S. children will develop otitis media at least once. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

In adults, acute otitis media can lead to such complications as **paralysis** of the facial nerves. Recovery from these complications may take from two weeks to as long as three months.

Causes and symptoms

The first precondition for the development of acute otitis media is exposure to an organism capable of causing the infection. Otitis media can be caused by either viruses or bacteria. Virus infections account for about 15% of cases. The three most common bacterial pathogens are *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis*. About 75% of ear infections caused by *S. pneumoniae* are reported to be penicillin-resistant.

Otitis media may also be caused by other disease organisms, including *Bordetella pertussis*, the causative agent of whooping **cough**, and *Pneumocystis carinii*, which often causes opportunistic infections in patients with **AIDS**.

There are other factors which make the development of an ear infection more likely. Because the eustachian tube has a more horizontal orientation and is considerably shorter in early childhood, material from the nasopharynx (including infection-causing organisms) is better able to reach the middle ear. Children also have a lot of lymph tissue (commonly called the adenoids) in the area of the eustachian tube. These adenoids may enlarge with repeated respiratory tract infections (colds), ultimately blocking the eustachian tubes. When the eustachian tube is blocked, the middle ear is more likely to fill with fluid. This fluid, then, increases the risk of infection, and the risk of **hearing loss** and delayed speech development.

Most cases of acute otitis media occur during the course of a URI. Symptoms include **fever**, ear pain, and problems with hearing. Babies may have difficulty feeding. When significant fluid is present within the middle ear, pain may increase depending on position. Lying down may cause an increase in painful pressure within the middle ear, so that babies may fuss if not held upright. If the fluid build-up behind the eardrum is sufficient, the eardrum may develop a hole (perforate),

WWW.BOOKBAZ.IR

causing bloody fluid or greenish-yellow pus to drip from the ear. Although pain may be significant leading up to such a perforation, the pain is usually relieved by the reduction of pressure brought on by a perforation.

Recent advances in gene mapping have led to the discovery of genetic factors that increase a child's susceptibility to otitis media. Researchers are hoping to develop molecular diagnostic assays that will help to identify children at risk for severe ear infections.

Diagnosis

Diagnosis is usually made simply by looking at the eardrum through a special lighted instrument called an otoscope. The eardrum will appear red and swollen, and may appear either abnormally drawn inward, or bulging outward. Under normal conditions, the ossicles create a particular pattern on the eardrum, referred to as "landmarks." These landmarks may be obscured. Normally, the light from the otoscope reflects off of the eardrum in a characteristic fashion. This is called the "cone of light." In an infection, this cone of light may be shifted or absent.

A special attachment to the otoscope allows a puff of air to be blown lightly into the ear. Normally, this should cause movement of the eardrum. In an infection, or when there is fluid behind the eardrum, this movement may be decreased or absent.

If fluid or pus is draining from the ear, it can be collected. This sample can then be processed in a laboratory to allow any organisms present to multiply sufficiently (cultured) to permit the organisms to be viewed under a microscope and identified.

Treatment

Medications

Antibiotics are the treatment of choice for acute otitis media (AOM). Different antibiotics are used depending on the type of bacteria most likely to be causing the infection. This decision involves knowledge of the types of antibiotics that have worked on other ear infections occurring within a particular community at a particular time. Options include sulfa-based antibiotics, as well as a variety of **penicillins**, **cephalosporins**, and others. The patient's sensitivity to certain medications, as well as previously demonstrated resistant strains, also contributes to the choice of antibiotic. A 0.3% topical solution of ofloxacin has been recommended as a more effective medication than other oral or **topical antibiotics**.

Some controversy exists regarding whether overuse of antibiotics is actually contributing to the development of bacteria, which may evolve and become able to avoid being killed by antibiotics. Research is being done to try to help determine whether there may be some ear infections that will clear up without antibiotic treatment. In the meantime, the classic treatment of an ear infection continues to involve a seven- to 10-day course of antibiotic medication.

Some medical practitioners prescribe the use of special nosedrops, **decongestants**, or **antihistamines** to improve the functioning of the eustachian tube.

Whether or not antibiotics are used, such pain relievers as Tylenol or Motrin can be very helpful in reducing the pain and inflammation associated with otitis media.

Surgery

In a few rare cases, a surgical perforation to drain the middle ear of pus may be performed. This procedure is called a myringotomy. The hole created by the myringotomy generally heals itself in about a week. In 2002 a new minimally invasive procedure was introduced that uses a laser to perform the myringotomy. It can be performed in the doctor's office and heals more rapidly than the standard myringotomy.

Although some doctors have recommended removing the adenoids to prevent recurrent otitis media in young children, recent studies indicate that surgical removal of the adenoids does not appear to offer any advantages over a myringotomy as a preventive measure.

Alternatives

Some practitioners believe that **food allergies** may increase the risk of ear infections, and they suggest eliminating suspected food allergens from the diet. The top food allergens are wheat, dairy products, corn, peanuts, citrus fruits, and eggs. Elimination of sugar and sugar products can allow the immune system to work more effectively. A number of herbal treatments have been recommended, including ear drops made with goldenseal (*Hydrastis canadensis*), mullein (*Verbascum thapsus*), St. John's wort (*Hypericum perforatum*), and **echinacea** (*Echinacea* spp.). Among the herbs often recommended for oral treatment of otitis media are echinacea and cleavers (*Galium aparine*), or black cohosh (*Cimicifuga racemosa*) and ginkgo (*Ginkgo biloba*). Homeopathic remedies that may be prescribed include aconite (*Acontium napellus*), *Ferrum phosphoricum,* belladonna, chamomile, *Lycopodium,* pulsatilla (*Pulsatilla nigricans*), or silica. **Craniosacral**

KEY TERMS

Adenoid—A collection of lymph tissue located in the nasopharynx.

Effusion—A collection of fluid which has leaked out into some body cavity or tissue.

Eustachian tube—A small tube which runs between the middle ear space and the nasopharynx.

Fomite—An inanimate object that can transmit infectious organisms.

Myringotomy—A surgical procedure performed to drain an infected middle ear. A newer type of myringotomy uses a laser instead of a scalpel.

Nasopharynx—The part of the airway into which the nose leads.

Ossicles—Tiny bones located within the middle ear which are responsible for conveying the vibrations of sound through to the inner ear.

Perforation—A hole.

Topical—Referring to a medication applied to the skin or outward surface of the body. Ear drops are one type of topical medication.

therapy uses gentle manipulation of the bones of the skull to relieve pressure and improve eustachian tube function.

Prognosis

With treatment, the prognosis for acute otitis media is very good. However, long-lasting accumulations of fluid within the middle ear are a risk both for difficulties with hearing and speech, and for the repeated development of ear infections. Furthermore, without treatment, otitis media can lead to an infection within the nearby mastoid bone, called **mastoiditis**.

Prevention

Although otitis media seems somewhat inevitable in childhood, some measures can be taken to decrease the chance of repeated infections and fluid accumulation. **Breastfeeding** provides some protection against URIs, which in turn protects against the development of otitis media. If a child is bottle-fed, parents should be advised to feed him or her upright, rather than allowing the baby to lie down with the bottle. General good hygiene practices (especially handwashing) help to decrease the number of upper respiratory infections in a household or daycare center.

The use of pacifiers should be avoided or limited. They may act as fomites (inanimate object that can transmit infectious organisms), particularly in a daycare setting. In children who are more susceptible to otitis media, pacifier use can increase by as much as 50% the number of ear infections experienced.

Two vaccines can prevent otitis media associated with certain strains of bacteria. One is designed to prevent **meningitis** and other diseases, including otitis media, that result from infection with *Haemophilus influenzae* type B. Another is a vaccine against *Streptococcus pneumoniae*, a very common cause of otitis media. Children who are at high risk or have had severe or chronic infections may be good candidates for these vaccines; in fact, a recent consensus report among pediatricians recommended routine administration of the pneumococcal conjugate vaccine to children younger than two years, as well as those at high risk for AOM. Parents should consult a healthcare provider concerning the advisability of this treatment.

Another vaccine that appears to lower the risk of AOM in children is the intranasal vaccine that was recently introduced for preventing **influenza**. Although the flu vaccine was not developed to prevent AOM directly, one team of researchers found that children who were given the vaccine before the start of flu season were 43% less likely to develop AOM than children who were not vaccinated.

As of early 2014, there is no vaccine effective against *M. catarrhalis*. Researchers are working on developing such a vaccine, as well as a tribacterial vaccine that would be effective against all three pathogens that commonly cause otitis media.

After a child has completed treatment for otitis media, a return visit to the practitioner should be scheduled. This visit should occur after the antibiotic has been completed, and allows the practitioner to evaluate the patient for the persistent presence of fluid within the middle ear. In children who have a problem with recurrent otitis media, a small daily dose of an antibiotic may prevent repeated full attacks of otitis media. In children who have persistent fluid, a procedure to place tiny tubes within the eardrum may help equalize pressure between the middle ear and the outside, thus preventing further fluid accumulation.

Otosclerosis

Definition

Otosclerosis is an excessive growth in the bones of the middle ear which interferes with the transmission of sound.

Description

The middle ear consists of the eardrum and a chamber which contains three bones called the hammer, the anvil, and the stirrup (or stapes). Sound waves passing through the ear cause the ear drum to vibrate. This vibration is transmitted to the inner ear by the three bones. In the inner ear, the vibrations are changed into impulses which are carried by the nerves, to the brain. If excessive bone growth interferes with the stapes ability to vibrate and transmit sound waves, **hearing loss** will result.

Otosclerosis is classified as a conductive disorder because it involves the bones of the ear. These bones conduct the sound to the nerve. If a person has hearing loss classified as neural, the nerve conducting the impulses to the brain is involved.

Otosclerosis is a common hereditary condition. About 10% of the Caucasion population has some form of otosclerosis, however, it is rare among other ethnic backgrounds. Women are more likely than men to suffer from otosclerosis. It is the most common cause of conductive hearing loss between the ages of 15–50, but if the bony growth affects only the hammer or anvil, there are no symptoms and the condition goes undetected. Disease affecting the stapes is also associated with progressive hearing loss.

Causes and symptoms

Otosclerosis is hereditary. Acquired illness and accidents have no relationship to its development.

KEY TERMS

Tinnitus—Tinnitus is noise originating in the ear, not in the environment. The noise can range from faint ringing to roaring.

The primary symptom of otosclerosis is loss of hearing. In addition, many people experience **tinnitus** (noice originating inside the ear). The amount of tinnitus is not necessarily related to the kind or severity of hearing loss.

Diagnosis

Hearing loss due to otosclerosis is usually first noticed in the late teens or early twenties. Hearing loss usually occurs in the low frequencies first, followed by high frequencies, then middle frequencies. Extensive hearing tests will confirm the diagnosis.

Treatment

People with otosclerosis often benefit from a properly fitted hearing aid.

The surgical replacement of the stapes has become a common procedure to improve conductive hearing problems. During this operation, called a **stapedectomy**, the stapes is removed and replaced with an artificial device. The operation is performed under local **anesthesia** and is usually an outpatient procedure. Surgery is done on only one ear at a time, with a one year wait between procedures. The degree of hearing improvement reaches its maximum about four months after the surgery. More than 80% of these procedures successfully improve or restore hearing.

Prognosis

People with otosclerosis almost never become totally deaf, and will usually be able to hear with a hearing aid or with surgery plus a hearing aid. In older people, the tendency for additional hearing loss is diminished due to the hardening of the bones.

Prevention

Otosclerosis cannot be prevented.

Otoscopic examination *see* **Ear exam with an otoscope**

Ototoxicity

Definition

Ototoxicity is damage to the hearing or balance functions of the ear by drugs or chemicals.

Description

Ototoxicity is drug or chemical damage to the inner ear. This section of the ear contains both the hearing mechanism and the vestibulocochlear nerve, the nerve that sends hearing and balance information to the brain. Because of this, ototoxic drugs may cause lack of hearing, and loss of sense of balance.

The extent of ototoxicity varies with the drug, the dose, and other conditions. In some cases, there is full recovery after the drug has been discontinued. In other cases, the extent of damage is limited, and may even be too small to be noticed. This may occur in high-frequency **hearing loss**, where the damage to the ear makes it difficult to hear high pitched musical notes, but does not affect the ability to hear the spoken word, or carry on a conversation. In extreme cases, there may be permanent and complete deafness.

Although ototoxicity is undesirable, the ear damage can actually be used to help people with Ménière's disease. This is a disease of no known cause that is marked by sudden episodes of **dizziness** and vertigo. Other symptoms include a feeling of "fullness" in the ears, roaring in the ears, and ringing in the ears. While most people with this condition can be controlled with medication, about 10% require surgery. However, use of some ototoxic drugs can actually improve this condition, while causing less damage to the hearing mechanism than traditional treatments.

WWW.BOOKBAZ.IR

Causes and symptoms

Many drugs can cause ototoxicity.

Antibiotics

- amikacin (Amikin)
- streptomycin
- neomycin
- gentamicin (Garamycin)
- erythromycin (E-Mycin, Eryc)
- kanamycin (Kantrex)
- tobramycin (Nebcin)
- netilmycin (Netromycin)
- vancomycin (Vancocin)

Anti-cancer drugs

- cisplatin (Platinol AQ)
- bleomycin (Blenoxane)
- vincristine (Oncovin)

Diuretics

- acetazolamide (Diamox)
- furosemide (Lasix)
- bumetanide (Bumex)
- ethacrynic acid (Edecrine)

A number of other drugs and chemicals may also cause ototoxicity. **Aspirin** overdose causes ringing in the ears. The **antimalarial drugs** quinine and chloroquine may also cause ear damage. Among the environmental chemicals that can cause ear damage are tin, lead, mercury, carbon monoxide, and carbon disulfide. This list is not complete, and many other drugs and chemicals, such as industrial solvents, may cause ear problems.

Diagnosis

Ototoxicity often goes undiagnosed. This occurs when the hearing loss is slight, or when it is restricted to the higher frequencies. Patients may notice a change in their hearing, but it may not be significant enough to report.

In other cases, the loss of hearing may be very significant, or the ototoxicity may take the form of ringing in the ears, or other sensations.

When physicians are administering medications that are known to cause hearing loss, it is often recommended that the patient receive regular hearing tests. By monitoring hearing on a regular basis, it may be possible to discontinue the medication, or reduce the dose so that no further damage is done.

KEY TERMS

Antibiotic—Drugs that kill or inhibit the growth of bacteria.

Cochlea—A division of the inner ear.

Diuretic—A drug that increases water loss through increased urination.

Ménière's disease—A disorder of the membranous labyrinth of the inner ear that is marked by recurrent attacks of dizziness, tinnitus, and deafness—also called Ménière's syndrome. It is named after Prosper Ménière (1799–1862), a French physician who was among the first people to study diseases of the ear, nose, and throat.

Tinnitus—Ringing sounds in the ears.

Ototoxicity that causes loss of balance may be even more difficult to diagnose. These changes may take place gradually, over time, and may be confused with the effects of the condition the drugs are meant to treat. If ototoxicity is suspected, **balance tests** are available, including a platform balance test, and a rotary chair. These, and other tests, determine how a patient responds to motion and changes in body position.

Treatment

There are no current treatments to reverse the effects of ototoxicity.

People who suffer permanent hearing loss may elect to use **hearing aids**, or, when appropriate, receive a cochlear implant. For those who have balance problems, **physical therapy** may often be helpful. Physical therapists can help people with balance problems learn to rely more on vision and the sensations from muscles to achieve balance.

Prognosis

The prognosis depends on the drugs that caused the ototoxicity, and their dose.

The aminoglycoside **antibiotics**, gentamicin, kanamycin, netilmycin and tobramycin all cause hearing loss to varying degrees. These drugs may be used to treat life-threatening infections that are resistant to other classes of drugs, and so there may be no choice but to use them. Careful dosing can minimize, but not eliminate the risk. It is estimated that the chances of recovery are 10–15%. The hearing loss usually begins at the higher frequencies, and is usually not recognized immediately.

Erythromycin may cause hearing loss that affects all frequencies. This hearing loss usually reverses itself over time.

Aspirin and the non-steroidal anti-inflammatory drugs (NSAIDS) may cause ringing in the ears (**tinnitus**). This stops when the drug is discontinued.

The **diuretics** may cause a hearing loss with a rapid onset. This will usually, but not always, reverse itself when the drugs are stopped.

In some cases, the prognosis is not really clear. Vancomycin appears to cause hearing loss, but this may only occur when vancomycin is used at the same time as other ototoxic drugs, such as gentamicin or erythromycin.

Prevention

Since most ototoxicity occurs when the harmful drugs are used in high doses, careful dose calculations are the best method of prevention. Sometimes it is possible to replace the ototoxic drugs with drugs that have less severe adverse effects.

Ovarian cancer

Definition

Ovarian cancer is cancer of the ovaries, the egg-releasing and hormone-producing organs of the female reproductive tract. In ovarian cancer, malignant (cancerous) cells divide and multiply in an uncontrolled, abnormal fashion to form a tumor.

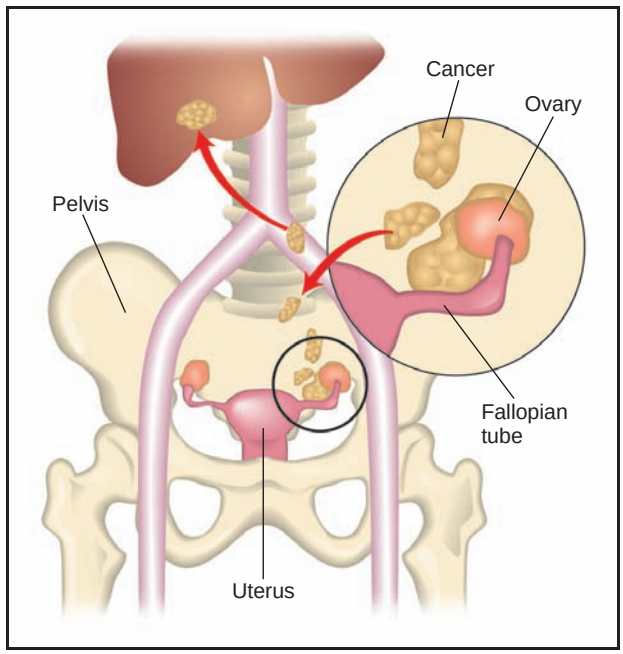

Diagram of the pelvic region with a cancerous growth on the ovary. *(Illustration by PreMediaGlobal. © Cengage Learning®.)*

Description

The ovaries are small almond-shaped organs located in the pelvic region, one on either side of the uterus. During a woman's childbearing years, the ovaries generally alternate to produce and release one egg each month as part of the normal menstrual cycle. The released egg is shunted into the adjacent fallopian tube and moves downward to the uterus where, if fertilized, it implants and develops into an embryo and if unfertilized is shed along with menstrual blood. The ovaries also secrete the female hormones estrogen and progesterone, which help regulate the menstrual cycle and **pregnancy**, as well as support the development of the secondary female sexual characteristics (i.e., breasts, overall body shape, vocal pitch, and body hair). During pregnancy and when women take certain medications, mainly **oral contraceptives**, the ovaries do not produce eggs.

Types of ovarian tumors

The ovaries contain three main types of cells: epithelial cells, stromal cells, and germ cells. About 90% of all ovarian cancers develop from epithelial cells lining the surface of the ovaries. About 15% of tumors that develop from epithelial cells are

WWW.BOOKBAZ.IR

considered to be low malignant potential (LMP) tumors. These tumors occur more often in younger women, are more likely to be diagnosed early, and thus have a better prognosis.

Stromal cells are located inside the ovary and produce the hormones estrogen and progesterone. About 1% of ovarian cancers begin in the stromal cells.

Germ cells also are located within the ovary. **Germ cell tumors** develop in the cells that would become eggs (ova). They account for about 2% of ovarian tumors. Many germ cell tumors are benign (noncancerous). These tumors often occur in teenaged girls and young women. The prognosis is good if they are found early, but as with other ovarian cancers, early detection is difficult.

Risk factors

Age is one of the greatest risk factors in developing ovarian cancer, with risk increasing after **menopause**. Another risk factor is a family or personal history of cancers of the female reproductive tract or breast that is caused by an inherited mutation in the genes *BRCA1* or *BRCA2*. Not all women with *BRCA1* or *BRCA2* mutations develop ovarian cancer. By age 70, a woman who has the *BRCA1* mutation carries about a 40–60% risk of developing ovarian cancer. Women with the mutation in *BRCA2* have a 15% risk of developing ovarian cancer. However, these gene mutations play a role in only about 5% of all ovarian cancer cases.

Another inherited syndrome that increases a woman's risk of ovarian cancer is hereditary nonpolyposis colorectal cancer or HNPCC. It is also called Lynch syndrome. While the greatest risk of HNPCC is colorectal cancer, women with the syndrome have a 12% lifetime risk of developing ovarian or uterine cancer. Up to 1% of all ovarian epithelial cancers are caused by Lynch syndrome.

Less common genetic disorders that increase a woman's risk of ovarian cancer include:

- Cowden's disease. Women with this disease have thyroid problems and an increased risk of breast cancer as well as ovarian cancer. Cowden's disease is caused by mutations in the *PTEN* gene.
- Peutz-Jeghers syndrome. Also called hereditary intestinal polyposis syndrome, this genetic disorder is caused by a mutation in the *STK11* gene and characterized by brown freckles around the mouth and benign polyps known as hamartomas in the digestive tract. People with this syndrome are at greatly increased risk of colon cancer as well as ovarian cancer and at a relatively young age.
- *MUTYH*-associated polyposis. Women with this syndrome develop small polyps in the colon and small intestine. They are at increased risk of colon cancer as well as ovarian cancer. The syndrome is caused by a mutation in the *MUTYH* gene.

Early menarche (first menstruation; before age 12) and late menopause also seem to put women at a higher risk of ovarian cancer. Other risk factors include eating a diet high in saturated fats; treatment with androgens (male hormones); treatment with the fertility drug clomiphene citrate for longer than a year; never having been pregnant (nulliparity); or having the first child after age 30. Conversely, having been pregnant, **breastfeeding**, and using oral contraceptives decrease the risk of developing ovarian cancer. It has been suggested that taking **aspirin** or **acetaminophen** lowers the risk of ovarian cancer, but this association had not been proven as of 2014.

Other risk factors for ovarian cancer include:

- Family history: having a first-degree relative (mother or sister) with ovarian cancer
- Obesity
- Use of hormone replacement therapy (HRT) for treating symptoms of menopause

Demographics

Ovarian cancer can develop at any age, but it is most likely to occur in women who are 50 years or older; most women are diagnosed after menopause. More than half the cases of ovarian cancer are among women who are over age 63. Industrialized countries have the highest incidence of ovarian cancer. Caucasian women, especially those of Ashkenazi Jewish descent, are at somewhat higher risk. African American and Asian women are at a slightly lower risk.

In 2014, ovarian cancer was the ninth most common cancer among women in the United States. It accounted for about 2.8% of all new cancers in American women. However, because of poor early detection, ovarian cancer is the fifth most common cause of cancer death among women. About one in 71 American women develops ovarian cancer during her lifetime, and one in 95 dies from it. The rate of new cases of ovarian cancer in the United States declined at the rate of about 1% per year between 2006 and 2014, and the death rate declined about 1.6% each year between 2001 and 2014. Rates were thought to be similar worldwide. The American Cancer Society estimated about 21,980 new cases of ovarian cancer

KEY TERMS

Adjuvant therapy—Treatment involving radiation, chemotherapy (drug treatment), hormone therapy, biotherapeutics, or a combination of any of these given after the primary treatment in order to rid the body of residual microscopic cancer.

Ascites—Accumulation of fluid within the peritoneal cavity.

Biomarker—A biochemical substance that can be detected in blood samples and indicates the presence of a cancerous tumor.

Debulking—The surgical removal of part of a cancerous tumor that cannot be completely excised, in order to improve the effectiveness of radiation therapy or chemotherapy.

Estrogen—Any of several steroid hormones, produced mainly in the ovaries, that stimulate the development of the endometrium and the development of female secondary sexual characteristics.

Hysterectomy—Surgical removal of the uterus.

Lymphatic system—A connected network of nodes, or glands that carry lymph throughout the body. Lymph is a fluid that contains the infection-fighting white blood cells that form part of the body's immune system. Because the network goes throughout the body, cancer cells that enter the lymphatic system can travel to and be deposited at any point into the tissues and organs and form new tumors there.

Menarche—The medical term for a girl's first menstrual period.

Omentum—The layer of peritoneal tissue that covers the abdominal organs. Its name comes from the Latin word for apron.

Oophorectomy—Surgical removal of the ovary.

Pap (Papanicolaou) smear (Pap test)—Removal of cervical cells to screen for cancer. The test was invented by and named for Greek physician George Papanicolaou, who was an early pioneer in cancer detection.

Placebo—A pill or liquid given during the study of a drug or dietary supplement that contains no medication or active ingredient. Usually study participants do not know if they are receiving a pill containing the drug or an identical-appearing placebo.

Targeted therapy—In cancer treatment, a type of drug therapy that blocks tumors by interfering with specific molecules that the cancer cells need for growth. Also called biologic therapy, targeted therapy is less harmful to normal cells than traditional chemotherapy.

would be diagnosed in the United States in 2014 and that cancer would cause about 14,270 deaths that year.

Causes and symptoms

Cells in ovarian tissue normally divide and grow according to controls and instructions by proteins produced by various genes. If certain genes develop changes (mutations), instructions for cellular growth and division may go awry. Abnormal, uncontrolled cell growth may occur, causing cancer. Most of these genetic changes are not inherited. Instead, they are sporadic, still unexplained changes. Most ovarian cancers occur later in life after years of exposure to various environmental factors (e.g., the body's own hormones, asbestos exposure, or **smoking**) that may cause sporadic genetic alterations.

Ovarian cancer often is called a silent killer because it produces few symptoms in its early stages. Only 20% of ovarian cancers are diagnosed early. Most women are unaware they have the disease until it has progressed to advanced stages. Most early symptoms are vague and either abdominal or gastrointestinal in nature. These symptoms may not be properly diagnosed or may be recognized as ovarian in nature only after a significant length of time has passed and ovarian cancer has advanced.

The following symptoms are possible indications of ovarian cancer, although these symptoms may also be due to many other causes. Symptoms that persist for two to three weeks or symptoms that are unusual for a particular woman should be evaluated by a doctor.

- such digestive symptoms as gas, indigestion, constipation, or a feeling of fullness after a light meal
- bloating, distention or cramping
- abdominal or low-back discomfort
- pelvic pressure or frequent urination
- unexplained changes in bowel habits
- nausea or vomiting
- pain or swelling in the abdomen
- loss of appetite
- fatigue

WWW.BOOKBAZ.IR

- unexplained weight gain or loss
- pain during intercourse
- vaginal bleeding in postmenopausal women

Diagnosis

In the best-case scenario a woman is diagnosed with ovarian cancer while it is still contained in just one ovary. Early detection can bring five-year survival to about 93%. Unfortunately, about three out of four women have advanced ovarian cancer at the time of diagnosis. Advanced ovarian cancer is at stage III or stage IV, and it has already spread (metastasized) to other organs. A **physical examination** and **pelvic exam** generally do not reveal early-stage ovarian cancer.

Tests

If ovarian cancer is suspected, several of the following tests and examinations are necessary to make a definitive diagnosis.

- a complete medical history to assess all risk factors
- a thorough bimanual pelvic examination
- CA-125 assay
- one or more various imaging procedures
- a lower GI series, or barium enema
- diagnostic laparoscopy for definitive diagnosis

BIMANUAL PELVIC EXAMINATION. The exam should include palpating (feeling) the following organs for any abnormalities in shape or size: the ovaries, fallopian tubes, uterus, vagina, bladder, and rectum. Because the ovaries are located deep within the pelvic area, it is unlikely that a manual exam will detect any abnormality while the cancer is still localized. A full examination, however, provides the practitioner with a more complete picture. An enlarged ovary does not confirm cancer, as the ovary may be large because of a cyst or **endometriosis**. While women should have an annual **Pap test** to detect **cervical cancer**, this test is ineffective in detecting ovarian cancer.

CA-125 ASSAY. The CA-125 assay is a blood test to determine the level of CA-125 (cancer antigen-125), a biomarker or tumor marker. A tumor marker is a measurable protein-based substance given off by the tumor. A series of CA-125 tests may be done to see if the amount of the marker in the blood is stable, increasing, or decreasing. A rising CA-125 level often indicates cancer, whereas a stable or declining value is more characteristic of a cyst. The CA-125 level should never be used alone to diagnose ovarian cancer. It can be normal in 50% of women with early-stage ovarian cancer. It is elevated in about 80% of women with late-stage ovarian cancer, but in 20% of cases it is not elevated. In addition, this is a general biomarker and can be elevated because of a non-ovarian cancer or from such nonmalignant gynecologic conditions as endometriosis or **ectopic pregnancy**. During menstruation the CA-125 level may be elevated, so the test is best done when the woman is not menstruating.

Other biomarkers that may be measured include human chorionic gonadotropin (HCG), alpha-fetoprotein (AFP), or lactate dehydrogenase (LDH), if the patient is suspected of having a germ cell ovarian tumor. High levels of estrogen and testosterone may point to a stromal tumor.

IMAGING. Several different imaging techniques are used in evaluating ovarian cancer. **Ultrasound** uses high-frequency sound waves that create a visual pattern of echoes of the structures at which they are aimed. It often can distinguish between a fluid-filled structure such as a cyst and a solid structure, such as a tumor. Ultrasound is painless and harmless; it is the same technique used to check a developing fetus in the womb. Ultrasound may be done externally through the abdomen and lower pelvic area or with a transvaginal probe (**transvaginal ultrasound**).

Other painless imaging techniques are computed tomography (CT) and **magnetic resonance imaging** (MRI). Color Doppler analysis provides additional contrast and accuracy in distinguishing masses. A **positron emission tomography** (PET) scan may also be used to look for metastatic ovarian cancer. PET scans involve the use of radioactive glucose to look for cancer cells, as cancers take up sugar more rapidly than normal tissues. These imaging techniques allow better visualization of the internal organs and can detect abnormalities without having to perform surgery.

LOWER GI SERIES. A lower GI series, or **barium enema**, uses a series of x rays to highlight the colon and rectum. To provide contrast, the patient drinks a chalky liquid containing barium. This test might be done to see if cancer has spread to these areas.

DIAGNOSTIC LAPAROSCOPY. This technique uses a thin hollow lighted instrument inserted through a small incision in abdomen to visualize the organs inside the abdominal cavity. If the ovary is believed to be malignant, the entire ovary may be removed (**oophorectomy**) and its tissue sent for evaluation to the pathologist, even though only a small piece of the tissue is needed for evaluation. If cancer is present, great care must be taken not to cause the rupture of the malignant tumor, as this could spread cancer cells to adjacent organs. If the cancer is completely contained in the ovary, its removal also functions as the treatment. If the cancer has spread or is suspected to have spread, then a saline solution

may be instilled into the cavity and then drawn out again. This technique is called peritoneal lavage. The aspirated fluid is evaluated for the presence of cancer cells. If peritoneal fluid is present—a condition called ascites—a sample of this material is also drawn and examined for malignant cells. If cancer cells are present in the peritoneum, then treatment is directed at the abdominal cavity as well.

Treatment

Treatment is based on the stage of cancer at diagnosis and the woman's age.

Clinical staging

Staging is the term used to determine whether the cancer is localized or has spread and, if so, how far and to which region(s) of the body. Staging helps define the cancer and determines the course of suggested treatment. Staging involves examining any tissue samples (biopsies) that have been taken from the ovary, nearby lymph nodes, and any structures where metastasis may be suspected. This may include the diaphragm, lungs, stomach, intestines, and omentum (the tissue covering internal organs), and any fluid, as described above.

The National Cancer Institute Stages uses the Tumor/Node/Metastasis (TNM) system for staging ovarian cancer. Other staging systems such as the International Federation of Gynecology and Obstetrics (FIGO) staging system also may be used. The TNM staging system is summarized as follows:

- Stage I: Cancer is confined to one or both ovaries.
- Stage II: Cancer is found in one or both ovaries and/or has spread to the uterus, fallopian tubes, and/or other body parts within the pelvic cavity. It has not spread to lymph nodes, the lining of the abdomen, or distant sites.
- Stage III: Cancer is found in one or both ovaries and has spread to lymph nodes or other body parts within the abdominal cavity, such as the surfaces of the liver or intestines.
- Stage IV: Cancer is found in one or both ovaries and has spread to such other distant organs as the lungs or the interior of the liver.

Individual stages are further subdivided; the FIGO subdivision of the stages was revised in January 2014. Accurate staging is important in determining a treatment plan.

Surgery

Surgery is done to remove as much of the tumor as possible (called tissue debulking), usually followed by **chemotherapy** and/or radiation (adjuvant therapy) to target cancer cells that have remained in the body without jeopardizing the woman's health. This can be hard to achieve once the cancer has spread. Removal of the ovary is called oophorectomy; removal of both ovaries is called bilateral oophorectomy. Unless it is very clear that the cancer has not spread, the fallopian tubes are removed as well (**salpingo-oophorectomy**). Removal of the uterus is called **hysterectomy**.

If a woman is young and wishes to have children, all attempts are made to spare the uterus. It is crucial that a woman discuss with her surgeon her childbearing plans before surgery. Ovarian cancer spreads easily and often spreads swiftly throughout the reproductive tract, so it may be necessary to remove all reproductive organs as well as part of the lining of the peritoneum to provide the woman with the best possible chance of long-term survival. Fertility-sparing surgery can be successful if the ovarian cancer is diagnosed very early.

Side effects of the surgery depend on the extent of the surgery but may include **pain** and temporary difficulty with bladder and bowel function, as well as reaction to the loss of hormones produced by the organs removed. A hormone replacement patch may be applied to the woman's skin in the recovery room to help with the transition. An emotional side effect involves the feeling of loss stemming from the removal of reproductive organs.

Chemotherapy

Chemotherapy is used to target cells that have traveled to other organs and throughout the body via the lymphatic system or the blood stream (metastasized). Chemotherapy drugs are designed to kill cancer cells, but they also harm healthy cells. Chemotherapy may be administered through a vein in the arm (intravenous, IV), may be taken in tablet form (orally), and/or may be given through a thin tube called a catheter directly into the abdominal cavity (intraperitoneal). IV and oral chemotherapy drugs travel throughout the body; intraperitoneal chemotherapy is localized in the abdominal cavity.

Side effects of chemotherapy vary greatly depending on the drugs used. As of 2014, chemotherapy drugs were often used in combinations to treat advanced ovarian cancer, and usually the combination included a platinum-based drug (such as cisplatin) with a taxol agent, such as paclitaxel. Combinations used or being studied included: carboplatin/paclitaxel, cisplatin/paclitaxel, cisplatin/topotecan, and cisplatin/carboplatin. Such antineoplastic agents as topotecan (Hycamtin)

WWW.BOOKBAZ.IR

or gemcitabine (Gemzar) that interfere with the ability of the tumor cells to reproduce also might be given. Other drugs that have been used to treat ovarian cancer include melphalan, ifosfamide, pemetrexed, and vinorelbine. Two newer chemotherapy drugs for ovarian cancer were trabectedin and belotecan.

The goal of chemotherapy is to maximize effectiveness with minimum side effects. Side effects include **nausea and vomiting**, **diarrhea**, decreased appetite and resulting weight loss, **fatigue**, headaches, loss of hair, and **numbness and tingling** (parethesia) in the hands or feet. Managing these side effects is an important part of cancer treatment.

After the full course of chemotherapy has been given, the surgeon may perform a second-look surgery to examine the abdominal cavity again to evaluate the success of treatment.

Radiation

Radiation uses high-energy, highly focused x rays to target very specific areas of cancer. This is done using a machine that generates an external energy beam. Careful measurements are taken so that the targeted area can be as focused and small as possible. Another form of radiation uses a radioactive liquid that is administered into the abdominal cavity in the same fashion as intraperitoneal chemotherapy. Radiation usually is given on a daily Monday-through-Friday schedule and for several weeks. Radiation is not painful, but side effects can include skin damage at the area exposed to the external beam and extreme fatigue. Fatigue may hit suddenly around the third week of treatment and may take a while to resolve even after treatments have terminated. Other side effects may include nausea, **vomiting**, diarrhea, loss of appetite, weight loss, and urinary difficulties. For patients with incurable ovarian cancer, radiation may be used to shrink tumor masses to provide pain relief and improve quality of life (**palliative care**).

Following treatment, regular follow-up appointments are scheduled to monitor for any long-term side effects, relapse, or metastases.

Targeted therapy

Targeted therapy is a newer form of pharmacotherapy that treats cancers with drugs that target the changes in genes or proteins that cause cancer cells to grow and spread. As of 2014, targeted therapy was most often used to treat advanced or metastatic ovarian cancer. The drug most often used to treat ovarian cancer is bevacizumab, a drug that works by blocking the growth of new blood vessels that nourish the tumor. It can be given together with chemotherapy. Although bevacizumab was approved by the Food and Drug Administration (FDA) to treat other cancers, it was not approved specifically for the treatment of ovarian cancer as of 2014. Other targeted therapy drugs were being researched; pazopanib was a newer drug in this class that showed promise in treating ovarian cancer.

Hormone therapy

Hormone therapy is used more often to treat stromal tumors than other types of ovarian cancer. The patient may be given luteinizing hormone-releasing hormone (LHRH) agonists. These drugs work by opposing the production of estrogen in the ovaries and are given to premenopausal women. They include leuprolide and goserelin. Tamoxifen is another drug with anti-estrogen activity that may be used to keep any estrogens circulating in the woman's bloodstream from stimulating the growth of new cancer cells. The third group of drugs used in hormone therapy for ovarian cancer is known as aromatase inhibitors. They block the enzyme aromatase from turning other hormones in the woman's body into estrogen. The aromatase inhibitors include letrozole, exemestane, and anastrozole.

Clinical trials

Clinical trials are human research studies. Their goal is to evaluate the effectiveness of new ways to treat cancer. There are many different designs, and they target different aspects of care. For example, some may investigate the response of different chemotherapy drugs, whereas another study may compare different types of treatment/chemotherapy combinations.

Research studies often are designed to compare the effectiveness of a new treatment method against the standard method or the effectiveness of a drug against a placebo (an inert substance that would be expected to have no effect on the outcome). Since the research is experimental in nature, there are no guarantees about the outcome. New drugs being used may have harmful, unknown side effects. Some people participate to help further knowledge about their disease. For others, the study may provide a possible treatment that is not yet available otherwise. Although there is no cost to participate, participants have to meet certain criteria before being admitted into the study. It is important to fully understand one's role in the study and weigh the potential risks versus benefits when deciding whether to participate.

Alternatives

The term *alternative therapy* refers to therapy used instead of conventional treatment. By definition, these treatments have not been scientifically proven or investigated as thoroughly and by the same standards as conventional treatments. The terms *complementary* or *integrative therapy* denote practices used in conjunction with rather than instead of conventional treatment. Patients should inform their doctors of any alternative or complementary therapies being used or considered as some alternative and complementary therapies adversely affect the effectiveness of conventional treatments. Some common complementary and alternative medicine therapies are:

- prayer and faith healing
- meditation
- such mind/body techniques as support groups, visualization, guided imagery, and hypnosis
- Therapeutic Touch, Reiki, and other energy therapies
- acupuncture and traditional Chinese medicine
- yoga, massage, and t'ai chi
- vitamin, mineral, and/or herbal supplements
- special diets, such as vegetarian, vegan, or macrobiotic

Coping with cancer treatment

Although the cancer may be in only a part of the body, it is very much a full mind/body experience. Strategies for coping with the treatment need to address the entire range of the experience. Women have different needs. Some might want to create a personal support team of friends. They can provide support in the following ways:

- Finding helpful information in the library or on the Internet about clinical trials, new therapies or treatments, different treatment centers.
- Providing transportation to and from appointments. A diagnosis of cancer can be overwhelming. In such a stressful and distracted state it is often hard to remember what a doctor has said or remember the questions to be asked. Having a listening companion during this stressful time can be helpful.
- Helping with household duties so that the woman can rest after treatments and have more energy to devote to her family.
- Assisting with childcare. Children are very much affected by a parent's cancer diagnosis, whether or not they understand what is taking place. For a child to go to a friend's house can provide a sense of normalcy and security.
- Being available to participate in activities and conversations not centering on the cancer. While in the midst of cancer treatments, it is important to talk about non-cancer issues as well and to maintain social relationships and activities.

A woman may wish to join a support group whose members also have or have had ovarian cancer. This group can provide a forum for talking about the diagnosis, treatments, side effects, and impact the diagnosis has on the patient. If there is no support group nearby, she may be able to join one on the Internet. Support groups also may exist for caregivers and loved ones.

Prognosis

The prognosis of ovarian cancer depends largely on the stage at which it is first diagnosed. Stage I ovarian cancer has the best survival rate, although ovarian cancer is rarely diagnosed at this stage. The 2014 five-year survival rates for the four stages of ovarian cancer are: stage I, 92.3%; stage II, 66%; stage III, 37%; stage IV, 18%.

Prevention

Since the cause of ovarian cancer is not known, it is not possible to fully prevent the disease. However, there are ways to reduce one's risks of developing the disease.

Decrease ovulation

Pregnancy temporarily stops ovulation, and multiple pregnancies appear to further reduce the risk of ovarian cancer. The research is not clear as to whether the pregnancy must result in a term delivery to have full benefit. Women who breastfeed their children also appear to have a lower risk of developing the disease. Since oral contraceptives also suppress ovulation, women who take birth-control pills have a lower incidence of ovarian cancer. It appears that the longer a woman takes oral contraceptives, the lower her risk of ovarian cancer. However, since oral contraceptives alter a woman's hormonal status, her risk for other hormonally related cancers may change. The woman should discuss the risks and benefits of oral contraceptives with her healthcare provider.

Genetic testing

Genetic testing is available that can help determine whether a woman who carries certain genes that increase her risk of breast and ovarian cancer. If the woman tests positive for a *BRCA1* or *BRCA2* mutation, then she may be able to consider having her ovaries removed as a preventive measure (prophylactic oophorectomy).

WWW.BOOKBAZ.IR

Surgery

Such procedures as **tubal ligation** (in which the fallopian tubes are blocked or tied) and hysterectomy (in which the uterus is removed) appear to reduce the risk of ovarian cancer. However, any removal of the reproductive organs has surgical as well as hormonal side effects.

Screening

There were no definitive tests or screening procedures approved by the FDA as of late 2014 to detect ovarian cancer in its early stages. Women at high risk should consult their physicians about possible regular screenings, which may include transvaginal ultrasound and a blood test for the CA-125 protein. The American Cancer Society recommends annual pelvic examinations for all women after age 40, in order to increase the chances of early detection of both cervical and ovarian cancer.

Early detection remains the key focal point in increasing survival rates for ovarian cancer because the more ovarian cancer has spread, the poorer the chance for survival past one or two years. As women and healthcare practitioners become more alert to vague early warning signs and seek more accurate family histories, earlier awareness may begin to lead to earlier detection and improved survival rates.

An ovarian cyst is being surgically removed from a 25-year-old female patient. *(Custom Medical Stock Photo, Inc.)*

Ovarian cysts

Definition

Ovarian cysts are sacs containing fluid or semi-solid material that develop in or on the surface of an ovary.

Description

Ovarian cysts are common, and the vast majority are harmless. Because they cause symptoms that may be the same as ovarian tumors that may be cancerous, ovarian cysts should always be checked out. The most common types of ovarian cysts are follicular and corpus luteum, which are related to the menstrual cycle. Follicular cysts occur when the cyst-like follicle on the ovary in which the egg develops does not burst and release the egg. They are usually small and harmless, disappearing within two to three menstrual cycles. Corpus luteum cysts occur when the corpus luteum—a small, yellow body that secretes hormones—does not dissolve after the egg is released. They usually disappear in a few weeks but can grow to more than 4 in (10 cm) in diameter and may twist the ovary.

Ovarian cysts can develop at any time in a female's life from infancy to **puberty** to **menopause**, including during **pregnancy**. Follicular cysts occur frequently during the years when a woman is menstruating, and are nonexistent in postmenopausal women or any woman who is not ovulating. Corpus luteum cysts occur occasionally during the menstrual years and during early pregnancy. (Dermoid cysts, which may contain hair, teeth, or skin derived from the outer layer of cells of an embryo, are also occasionally found in the ovary.)

Causes and symptoms

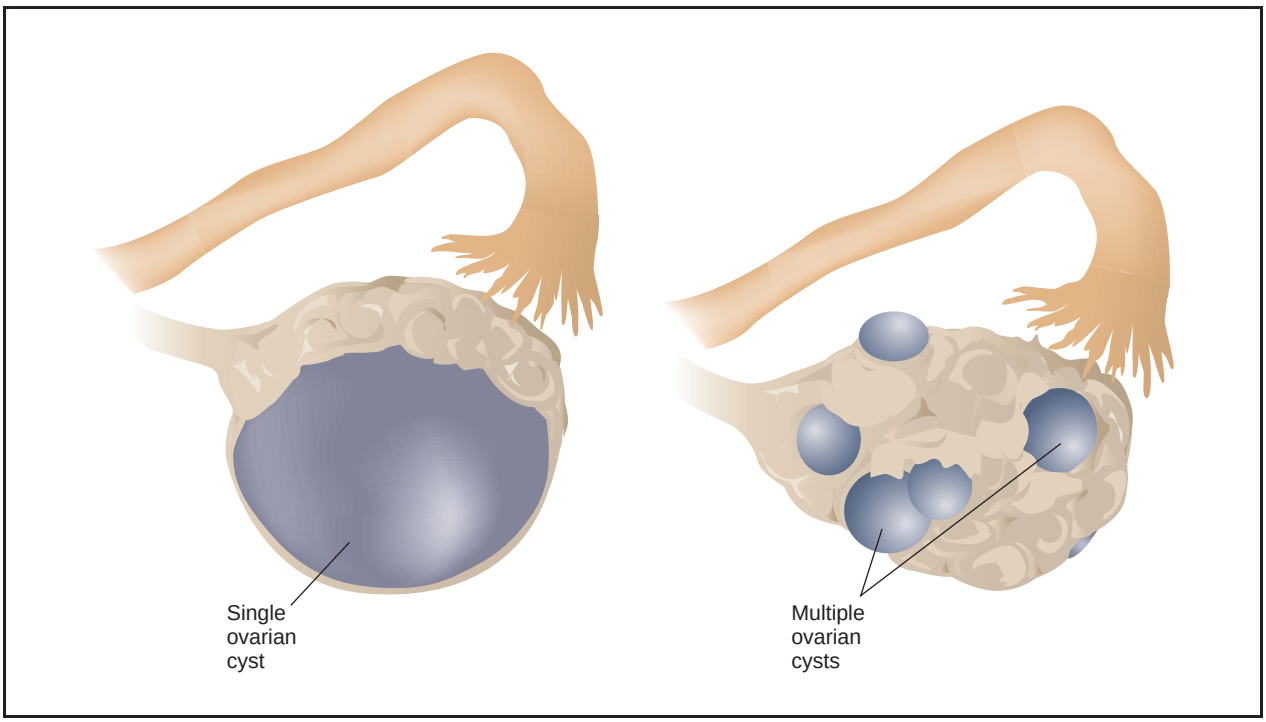
Causes

Follicular cysts are caused by the formation of too much fluid around a developing egg. Corpus luteum cysts are caused by excessive accumulation of blood during the menstrual cycle, hormone therapy, or other types of ovarian tumors.

There is also a condition known as **polycystic ovary syndrome** (PCOS) in which the eggs and follicles are not released from the ovaries and instead form multiple cysts. **Obesity** is linked to this condition, as 50% of women with PCOS are also obese. Hormonal imbalances play a major role in this condition, including high levels of the hormone androgen and low levels of progesterone, the female hormone necessary for egg release. High levels of insulin, the hormone that regulates blood sugar, are often found in women with PCOS. PCOS is also characterized by irregular menstrual periods, **infertility**, and **hirsutism** (excessive hair growth on the body and face). Although PCOS was formerly thought to be an adult-onset condition, more recent research indicates that it begins in childhood, possibly even during fetal development.

PCOS is also known to run in families, which suggests that genetic factors contribute to its development. The specific gene or genes responsible for PCOS have not yet been identified; however, several groups of researchers in different countries have been investigating genetic variations associated with increased risk of type 2 diabetes in order to determine whether the same genetic variations may be involved in PCOS.

WWW.BOOKBAZ.IR



(Illustration by Argosy, Inc. © Cengage Learning®.)

In adolescent girls, ovarian cysts may be associated with a genetic disorder known as McCune-Albright syndrome, which is characterized by abnormal bone growth, discoloration of the skin, and early onset of puberty. The ovarian cysts are responsible for the early sexual maturation.

As of early 2003, McCune-Albright syndrome was known to be associated with mutations in the GNAS1 gene. The mutation is sporadic, which means that it occurs during the child's development in the womb and that the syndrome is not inherited.

Symptoms

Many ovarian cysts have no symptoms. When the growth is large or there are multiple cysts, the patient may experience any of the following symptoms:

- Fullness or heaviness in the abdomen.
- Pressure on the rectum or bladder.
- Pelvic pain that is a constant dull ache and may spread to the lower back and thighs, occurs shortly before the beginning or end of menstruation, or occurs during intercourse.

Diagnosis

Non-symptomatic ovarian cysts are often felt by a doctor examining the ovaries during a routine **pelvic exam**. Symptomatic ovarian cysts are diagnosed through a pelvic exam and **ultrasound**. Ultrasonography is a painless test that uses a hand-held wand to send and receive sound waves to create images of the ovaries on a computer screen. The images are photographed for later analysis. It takes about 15 minutes and is usually done in a hospital or a physician's office.

Ovarian cysts can be diagnosed in female fetuses by transabdominal ultrasound during the mother's pregnancy.

Treatment

Watchful waiting

Many follicular and corpus luteum cysts require no treatment and disappear on their own. Often the physician will wait and re-examine the patient in four to six weeks before taking any action. Follicular cysts do not require treatment, but birth-control pills may be taken if the cysts interfere with the patient's daily activities.

Most uncomplicated ovarian cysts in female infants resolve on their own shortly after delivery. Complicated cysts are treated by **laparoscopy** or laparotomy after the baby is born.

KEY TERMS

Corpus luteum—A small, yellow structure that forms in the ovary after an egg has been released.

Cystectomy—Surgical removal of a cyst.

Dermoid—A skin-like benign growth that may appear on the ovary and resemble a cyst.

Endocrine—Internal secretions, usually in the systemic circulation.

Follicular—Relating to one of the round cells in the ovary that contain an ovum.

Hirsutism—A condition marked by excessive hair growth on the face and body.

Functional cyst—A benign cyst that forms on the ovary and resolves on its own without treatment.

McCune-Albright syndrome (MCAS)—A genetic syndrome characterized in girls by the development of ovarian cysts and puberty before the age of eight, together with abnormalities of bone structure and skin pigmentation.

Ovulation—The phase of the female monthly cycle when a developed egg is released from the ovary into the fallopian tube for possible fertilization.

Polycystic ovarian syndrome (PCOS)—A condition in which the eggs are not released from the ovaries and instead form multiple cysts.

Medications

McCune-Albright syndrome is treated with testolactone (Teslac), an anti-estrogen drug that corrects the hormonal imbalance caused by the ovarian cysts.

Long-term management of PCOS has been complicated in the past by lack of a clear understanding of the causes of the disorder. Most commonly, hormonal therapy has been recommended, including estrogen and progesterone and such other hormone-regulating drugs as ganirelix (Antagon). Birth-control pills have also been prescribed by doctors to regulate the menstrual cycle and to shrink functional cysts.

More recent studies have shown that increasing sensitivity to insulin in women with PCOS leads to improvement in both the hormonal and metabolic symptoms of the disorder. This sensitivity is increased by either weight loss and **exercise** programs or by medications. Metformin (Glucophage), a drug originally developed to treat type 2 diabetes, has been shown to be effective in reducing the symptoms of hyperandrogenism as well as **insulin resistance** in women with PCOS.

Another strategy that is being tried with PCOS is administration of flutamide (Eulexin), a drug normally used to treat **prostate cancer** in men. Preliminary results indicate that the antiandrogenic effects of flutamide benefit patients with PCOS by increasing blood flow to the uterus and ovaries.

Surgery

Surgery is usually indicated for patients who have not reached puberty and have an ovarian mass and in postmenopausal patients. Surgery is also indicated if the growth is larger than 4 in (10 cm), complex, growing, persistent, solid and irregularly shaped, on both ovaries, or causes **pain** or other symptoms. Ovarian cysts are curable with surgery but often recur without it.

Surgical options include removal of the cyst or removal of one or both ovaries. More than 90% of benign ovarian cysts can be removed using laparoscopy, a minimally invasive outpatient procedure. In laparoscopic **cystectomy**, the patient receives a general or local anesthetic, then a small incision is made in the abdomen. The laparoscope is inserted into the incision and the cyst or the entire ovary is removed. Laparoscopic cystectomy enables the patient to return to normal activities within two weeks. Surgical cystectomy to remove cysts and/or ovaries is performed under general **anesthesia** in a hospital and requires a stay of five to seven days. After an incision is made in the abdomen, the muscles are separated and the membrane surrounding the abdominal cavity (peritoneum) is opened. Blood vessels to the ovaries are clamped and tied. The cyst is located and removed. The peritoneum is closed, and the abdominal muscles and skin are closed with sutures or clips. Recovery takes four weeks.

A surgical procedure known as ovarian wedge resection appears to improve fertility in women with PCOS who have not responded to drug treatments. In an ovarian wedge resection, the surgeon removes a portion of the polycystic ovary in order to induce ovulation.

Alternatives

Alternative treatments for ovarian problems—herbal therapies, **nutrition** and diet, and homeopathy—should be used to supplement, not replace, conventional treatment. General herbal tonics for female reproductive organs that can be taken in tea or tincture (an alcohol-based herbal extract) form include blue cohosh (*Caulophylum thalictroides*) and false unicorn root (*Chamaelirium luteum*). Recommendations to help prevent and treat ovarian cysts include a vegan diet (no dairy or animal products) that includes beets,

WWW.BOOKBAZ.IR

carrots, dark-green leafy vegetables, and lemons; antioxidant supplements including zinc and **vitamins** A, E, and C; as well as black currant oil, borage oil, and evening primrose oil (*Oenothera biennis*) supplements. Homeopathic treatments—tablets, powders, and liquids prepared from plant, mineral, and animal extracts—may also be effective in treating ovarian cysts. Castor oil packs can help reduce inflammation. **Hydrotherapy** applied to the abdomen can help prevent rupture of the cyst and assist its reabsorption.

Prognosis

The prognosis for non-cancerous ovarian cysts is excellent.

Prevention

Ovarian cysts cannot be prevented.

Ovarian torsion

Definition

Ovarian torsion is the twisting of the ovary due to the influence of another condition or disease. This results in extreme lower abdominal **pain**.

Description

Ovarian torsion occurs infrequently only in females. In can occur in women of all ages, but most women who experience this are younger. Approximately 70–75% of cases occur in women under 30 years old. About 20% of all reported cases are in pregnant women. It is the fifth most common gynecological emergency which can include surgical intervention.

Ovarian torsion usually arises in only one ovary at a time. They can occur in either normal or enlarged ovaries and fallopian tubes, and occasionally they develop in both.

KEY TERMS

Congenital—Condition present at birth.

Laparoscopy—Endoscope used to observe structures in the abdomen.

Mesosalpinx—A ligament connected to the fallopian tube.

Ovary—Female reproductive gland that contains the ova (eggs).

Tachycardia—Rapidly beating heart.

Torsion—The action of twisting.

Causes and symptoms

A variety of conditions that can cause torsion of the ovary ranging from changes in normal ovaries to congenital and developmental abnormalities or even a disease that affects the tube or ovary. Normal ovaries that experience spasms or changes in the blood vessels in the mesosalpinx can become twisted. For example, if the veins in the mesosalpinx become congested, the ovaries will undergo torsion.

Developmental abnormalities of the fallopian tube such as extremely longer-than-normal tubes or a missing mesosalpinx will cause ovarian torsion. Diseases such as **ovarian cysts** or fibromas, tumor of the ovary or tubes, and **trauma** to either the ovaries or the tubes will also cause ovarian torsion.

The characteristic symptom of ovarian torsion is the sudden onset of extreme lower abdominal pain that radiates to the back, side and thigh. Nausea, **vomiting**, **diarrhea**, and **constipation** can accompany the pain. The patient may also experience tenderness in the lower abdominal area, a mild **fever** and tachycardia.

Diagnosis

The diagnosis of ovarian torsions usually occurs in an emergency room due to the suddenness of extreme pain. Emergency room physicians may consult with another physician specializing in obstetrics and gynecology. Since 20% of ovarian torsions occur in pregnant women, physicians will order a **pregnancy** test. Visualization with an **ultrasound** and CT scan (computed tomography) will help pinpoint the ovarian structures and allow physicians to diagnose. Diagnosis is often confirmed through **laparoscopy**.

Treatment

Ovarian torsions need to be repaired. This is done through surgery, and for less severe cases laparoscopic surgery is used. Medications such as NSAIDs are given to control pain.

Prognosis

If ovarian torsions are diagnosed and treated early, then the prognosis is favorable. However, if diagnosis is delayed, the torsions can worsen and cut off arterial blood flow into and venous blood flow out of the ovary. This results in necrosis (death) of the ovarian tissue. Delayed diagnosis can also result in problems when trying to conceive due to **infertility**.

Prevention

Currently, there are no known methods for prevention of ovarian torsion.

Overactive bladder

Definition

Overactive bladder is the leakage of large amounts of urine at unexpected times, including during sleep.

Description

People who lose urine for no apparent reason while suddenly feeling the need or urge to urinate may have overactive bladder. The condition effects 17 million in the United States. The most common cause of overactive bladder is inappropriate bladder contractions. Medical professionals describe such a bladder as "unstable," "spastic," or "overactive." A doctor might call the condition "reflex incontinence" if it results from overactive nerves controlling the bladder. Having an overactive bladder can mean that the bladder empties during sleep, after drinking a small amount of water, or when touching water or hearing it running (as when someone else is taking a shower or washing dishes). Involuntary actions of bladder muscles can occur because of damage to the nerves of the bladder, to the nervous system (spinal cord and brain), or to muscles themselves. **Multiple sclerosis**, Parkinson's disease, Alzheimer's disease, **stroke**, brain tumors, and injury—including injury

WWW.BOOKBAZ.IR

that occurs during surgery—all can harm bladder nerves or muscles.

Causes and symptoms

People with overactive bladder lose urine as soon as they feel a strong need to go to the bathroom. People with overactive bladder may leak urine:

- when they can not get to the bathroom quickly enough
- when they drink even a small amount of liquid
- when they hear or touch running water

People with overactive bladder may also go to the bathroom very often; for example, every two hours during the day and night. They may even wet the bed.

Diagnosis

To diagnose the problem, a doctor will first ask about symptoms and medical history. Other obvious factors that can help define the problem include straining and discomfort, use of drugs, recent surgery, and illness. If the patient's medical history does not define the problem, it will at least suggest which tests are needed. The doctor will physically examine the patient for signs of medical conditions causing the overactive bladder, such as tumors that block the urinary tract, stool impaction, and poor reflexes or sensations, which may be evidence of a nerve-related cause. Overactive bladder is often treated by general or family practicioners but the patient may be referred to a urologist, who specializes in the urinary tract, or a urogynecologist, who focuses on urological problems in women.

Common tests used to diagnose overactive bladder include:

- blood tests to examine blood for levels of various chemicals
- cystoscopy to look for abnormalities in the bladder and lower urinary tract. It works by inserting a small tube into the bladder that has a telescope for the doctor to look through.
- post-void residual (PVR) measurement to see how much urine is left in the bladder after urinating by placing a small soft tube into the bladder or by using ultrasound (sound waves)
- urinalysis to examine urine for signs of infection, blood, or other abnormalities
- urodynamic testing to examine bladder and urethral sphincter function (may involve inserting a small tube into the bladder; x rays also can be used to see the bladder)

KEY TERMS

Alzheimer's disease—A degenerative disorder that affects the brain and causes dementia, especially late in life.

Biofeedback—The use of monitoring devices that display information about the operation of a bodily function, for example, heart rate or blood pressure, that is not normally consciously controlled.

Cystoscopy—The use of a narrow tubular instrument that is passed through the urethra to examine the interior of the urethra and the urinary bladder.

Estrogen—Any of several steroid hormones, produced mainly in the ovaries, that stimulate estrus and the development of female secondary sexual characteristics.

Multiple sclerosis—A serious progressive disease of the central nervous system.

Parkinson's disease—An incurable nervous disorder marked by the symptoms of trembling hands, lifeless face, monotone voice, and a slow, shuffling walk.

Sphincter—A circular band of muscle that surrounds an opening or passage in the body and narrows or closes the opening by contracting.

Urethal—Referring to the tube in humans that carries urine from the bladder out of the body.

Urogynecologist—A physician that deals with women's health, especially with the health of women's reproductive organs and urinary tract.

Urologist—A physician who deals with the study and treatment of disorders of the urinary tract in women and the urogenital system in men.

Treatment

Medications can reduce many types of leakage. Some drugs inhibit contractions of an overactive bladder. Others, such as solifenacin succinate (Vesicare), relax muscles, leading to more complete bladder emptying during urination. Some drugs tighten muscles at the bladder neck and urethra, preventing leakage. Among the drugs used are oxybutynin (Ditropan XL), 5–30 mg daily; solifenacin (Vesicare), 5–10 mg a day; darifenacin (Enablex), 3.75–15 mg daily; and tolterodine (Detrol), 2–4 mg daily. A one-month supply of these drugs costs $90–125. Some medications, especially hormones such as estrogen, are believed to cause muscles involved in urination to function normally. Some of these medications can produce harmful side effects if used for long

periods. In particular, estrogen therapy has been associated with an increased risk for cancers of the breast and the lining of the uterus. Patients should talk to their doctor about the risks and benefits of long-term use of medications.

Alternatives

Adjusting dietary habits and avoiding acidic and spicy foods, alcohol, **caffeine**, and other bladder irritants can help to prevent urinary leaking. Eat recommended amounts of whole grains, fruits, and vegetables to avoid **constipation**. **Bladder training**, used to treat urge incontinence, can also be a useful treatment tool. The technique involves placing a patient on a toileting schedule. The time interval between urination is then gradually increased until an acceptable time period between bathroom breaks is consistently achieved.

Biofeedback techniques can teach overactive bladder patients to control the urge to urinate. Biofeedback uses sensors to monitor temperature and muscle contractions in the vagina to help overactive bladder patients learn to increase their control over the pelvic muscles.

An infusion, or tea, of horsetail *(Equisetum arvense)*, agrimony *(Agrimonia eupatoria)*, and sweet sumach *(Rhus aromatica)* may be prescribed by an herbalist or naturopath to an overactive bladder. These herbs are natural astringents, and encourage toning of the digestive and urinary tracts. Other herbs, such as urtica, or stinging nettle *(Urtica urens)*, plantain *(Plantago major)*, or maize *(Zea mays)* may be helpful. Homeopathic remedies may include pulsatilla and causticum. Chinese herbalists might recommend golden lock tea, a mixture of several herbs that helps the body retain fluids.

Prognosis

With proper treatment, the prognosis for controlling the disorder is very good. There is no cure for overactive bladder.

Prevention

There are no known preventative measures for overactive bladder.

Overhydration

Definition

Overhydration, also called water excess or water intoxication, is a condition in which the body contains too much water.

Description

Overhydration occurs when the body takes in more water than it excretes and its normal **sodium** level is diluted. This can result in digestive problems, behavioral changes, brain damage, seizures, or **coma**. An adult whose heart, kidneys, and pituitary gland are functioning properly would have to drink more than two gallons of water a day to develop water intoxication. This condition is most common in patients whose kidney function is impaired and may occur when doctors, nurses, or other healthcare professionals administer greater amounts of water-producing fluids and medications than the patient's body can excrete. Overhydration is the most common electrolyte imbalance in hospitals, occurring in about 2% of all patients.

Infants seem to be at greater risk for developing overhydration. The Centers for Disease Control and Prevention has declared that babies are especially susceptible to oral overhydration during the first month of life, when the kidneys' filtering mechanism is too

WWW.BOOKBAZ.IR

immature to excrete fluid as rapidly as older infants do. Breast milk or formula provide all the fluids a healthy baby needs. Water should be given slowly, sparingly, and only during extremely hot weather. Overhydration, which has been cited as a hazard of infant swimming lessons, occurs whenever a baby drinks too much water, excretes too little fluid, or consumes and retains too much water.

Causes and symptoms

Drinking too much water rarely causes overhydration when the body's systems are working normally. People with heart, kidney, or **liver disease** are more likely to develop overhydration because their kidneys are unable to excrete water normally. It may be necessary for people with these disorders to restrict the amount of water they drink and/or adjust the amount of salt in their **diets**.

Since the brain is the organ most susceptible to overhydration, a change in behavior is usually the first symptom of water intoxication. The patient may become confused, drowsy, or inattentive. Shouting and **delirium** are common. Other symptoms of overhydration may include blurred vision, **muscle cramps** and twitching, **paralysis** on one side of the body, poor coordination, **nausea and vomiting**, rapid breathing, sudden weight gain, and weakness. The patient's complexion is normal or flushed. Blood pressure is sometimes higher than normal, but elevations may not be noticed even when the degree of water intoxication is serious.

Overhydration can cause acidosis (a condition in which blood and body tissues have an abnormally high acid content), anemia, **cyanosis** (a condition that occurs when oxygen levels in the blood drop sharply), hemorrhage, and **shock**. The brain is the organ most vulnerable to the effects of overhydration. If excess fluid levels accumulate gradually, the brain may be able to adapt to them and the patient will have only a few symptoms. If the condition develops rapidly, confusion, seizures, and coma are likely to occur.

Risk factors

Chronic illness, **malnutrition**, a tendency to retain water, and kidney diseases and disorders increase the likelihood of becoming overhydrated. Infants and the elderly seem to be at increased risk for overhydration, as are people with certain mental disorders or **alcoholism**.

Diagnosis

Before treatment can begin, a doctor must determine whether a patient's symptoms are due to overhydration, in which excess water is found within and outside cells, or excess blood volume, in which high sodium levels prevent the body from storing excess water inside the cells. Overhydration is characterized by excess water both within and around the body's cells, while excess blood volume occurs when the body has too much sodium and cannot move water to reservoirs within the cells. In cases of overhydration, symptoms of fluid accumulation do not usually occur. On the other hand, in cases of excess blood volume, fluid tends to accumulate around cells in the lower legs, abdomen, and chest. Overhydration can occur alone or in conjunction with excess blood volume, and differentiating between these two conditions may be difficult.

Treatment

Mild overhydration can generally be corrected by following a doctor's instructions to limit fluid intake. In more serious cases, **diuretics** may be prescribed to increase urination, although these drugs tend to be most effective in the treatment of excess blood volume. Identifying and treating any underlying condition (such as impaired heart or kidney function) is a priority, and fluid restrictions are a critical component of every treatment plan.

In patients with severe neurologic symptoms, fluid imbalances must be corrected without delay. A powerful diuretic and fluids to restore normal sodium concentrations are administered rapidly at first. When the patient has absorbed 50% of the therapeutic substances, blood levels are measured. Therapy is continued at a more moderate pace in order to prevent brain damage as a result of sudden changes in blood chemistry.

Prognosis

Mild water intoxication is usually corrected by drinking less than a quart of water a day for several days. Untreated water intoxication can be fatal, but this outcome is quite rare.

Oxygen inhalation therapy *see* **Oxygen therapy**

Oxygen therapy

Definition

Oxygen may be classified as an element, a gas, and a drug. Oxygen therapy is the administration of oxygen at concentrations greater than that in room air to treat or prevent hypoxemia (not enough oxygen in the blood). Oxygen delivery systems are classified as stationary, portable, or ambulatory. Oxygen can be administered by nasal cannula, mask, and tent. **Hyperbaric oxygen therapy** involves placing the patient in an airtight chamber with oxygen under pressure.

Purpose

The body is constantly taking in oxygen and releasing carbon dioxide. If this process is inadequate, oxygen levels in the blood decrease, and the patient may need supplemental oxygen. Oxygen therapy is a key treatment in respiratory care. The purpose is to increase oxygen saturation in tissues where the saturation levels are too low due to illness or injury. Breathing prescribed oxygen increases the amount of oxygen in the blood, reduces the extra work of the heart, and decreases **shortness of breath**. Oxygen therapy is frequently ordered in the **home care** setting, as well as in acute (urgent) care facilities.

Some of the conditions oxygen therapy is used to treat include:

- documented hypoxemia
- severe respiratory distress (e.g., acute asthma or pneumonia)
- severe trauma
- chronic obstructive pulmonary disease (COPD, including chronic bronchitis, emphysema, and chronic asthma)
- pulmonary hypertension
- cor pulmonale
- acute myocardial infarction (heart attack)
- short-term therapy, such as postanesthesia recovery

Oxygen may also be used to treat chronic lung disease patients during **exercise**.

Hyperbaric oxygen therapy is used to treat the following conditions:

- gas gangrene
- decompression sickness
- air embolism
- smoke inhalation
- carbon monoxide poisoning
- cerebral hypoxic event

Helium-oxygen therapy is a treatment that may be used for patients with severe airway obstruction. The combination of helium and oxygen, known as heliox, reduces the density of the delivered gas, and has been shown to reduce the effort of breathing and improve ventilation when an airway obstruction is present. This type of treatment may be used in an emergency room for patients with acute, severe **asthma**.

Description

Oxygen delivery (other than mechanical ventilators and hyperbaric chambers)

In the hospital, oxygen is supplied to each patient room via an outlet in the wall. Oxygen is delivered from a central source through a pipeline in the facility. A flow meter attached to the wall outlet accesses the oxygen. A valve regulates the oxygen flow, and attachments may be connected to provide moisture. In the home, the oxygen source is usually a canister or air compressor. Whether in home or hospital, plastic tubing connects the oxygen source to the patient.

Oxygen is most commonly delivered to the patient via a nasal cannula or mask attached to the tubing. The nasal cannula is usually the delivery device of choice since it is well tolerated and doesn't interfere with the patient's ability to communicate, eat, or drink. The concentration of oxygen inhaled depends upon the prescribed flow rate and the ventilatory minute volume (MV).

Another delivery option is transtracheal oxygen therapy, which involves a small flexible catheter inserted in the trachea or windpipe through a tracheostomy tube. In this method, the oxygen bypasses the mouth, nose, and throat, and a humidifier is required at flow rates of 1

WWW.BOOKBAZ.IR

KEY TERMS

Atelectasis—Partial or complete collapse of the lung, usually due to a blockage of the air passages with fluid, mucus or infection.

Breathing rate—The number of breaths per minute.

Cannula—Also called nasal cannula. A small, lightweight plastic tube with two hollow prongs that fit just inside the nose. Nasal cannulas are used to supply supplemental oxygen through the nose.

Cyanosis—Blue, gray, or dark purple discoloration of the skin caused by a deficiency of oxygen.

Ductus arteriosus—A fetal blood vessel that connects the aorta and pulmonary artery.

Flow meter—Device for measuring the rate of a gas (especially oxygen) or liquid.

Hypoxemia—Oxygen deficiency, defined as an oxygen level less than 60 mm Hg or arterial oxygen saturation of less than 90%. Different values are used for infants and patients with certain lung diseases.

Oxygenation—Saturation with oxygen.

Peak expiratory flow rate—A test used to measure how fast air can be exhaled from the lungs.

Pulmonary function tests—A series of tests that measure how well air is moving in and out of the lungs and carrying oxygen to the bloodstream.

Pulmonary rehabilitation—A program that helps patients learn how to breathe easier and improve their quality of life. Pulmonary rehabilitation includes treatment, exercise training, education, and counseling.

Pulmonologist—A physician who specializes in caring for people with lung diseases and breathing problems.

Pulse oximetry—A noninvasive test in which a device that clips onto the finger measures the oxygen level in the blood.

Residual volume—The volume of air remaining in the lungs, measured after a maximum expiration.

Respiratory failure—The sudden inability of the lungs to provide normal oxygen delivery or normal carbon dioxide removal.

Respiratory therapist—A healthcare professional who specializes in assessing, treating, and educating people with lung diseases.

Total lung capacity test—A test that measures the amount of air in the lungs after a person has breathed in as much as possible.

Vital capacity—Maximal breathing capacity; the amount of air that can be expired after a maximum inspiration.

liter (2.1 pt) per minute and above. Other oxygen delivery methods include tents and specialized infant oxygen delivery systems.

TYPES OF OXYGEN DELIVERY SYSTEMS. The types of oxygen delivery systems include:

- Compressed oxygen is stored as a gas in a tank. A flow meter and regulator are attached to the oxygen tank to adjust oxygen flow. Tanks vary in size from very large to smaller, portable tanks. This system is generally prescribed when oxygen is not needed constantly (e.g., when it is only needed when performing physical activity).
- Liquid oxygen is stored in a large stationary tank that stays in the home. A portable tank is available that can be filled from the stationary tank for trips outside the home. Oxygen is liquid at very cold temperatures. When warmed, liquid oxygen changes to a gas for delivery to the patient.
- An oxygen concentrators is an electric oxygen delivery system approximately the size of a large suitcase. The concentrator extracts some of the air from the room, separates the oxygen, and delivers it to the patient via a nasal cannula. A cylinder of oxygen is provided as a backup in the event of a power failure, and a portable tank is available for trips outside the home. This system is generally prescribed for patients who require constant supplemental oxygen or who must use it when sleeping.
- Oxygen conserving devices, such as demand inspiratory flow systems or pulsed-dose oxygen delivery system, use sensors to detect when inspiration (inhalation) begins. Oxygen is delivered only upon inspiration, thereby conserving oxygen during exhalation. These systems can be used with either compressed or liquid oxygen systems, but are not appropriate for all patients.

Preparation

A physician's order is required for oxygen therapy, except in emergency use. The need for supplemental oxygen is determined by inadequate oxygen saturation, indicated in blood gas measurements,

pulse oximetry, or clinical observations. The physician will prescribe the specific amount of oxygen needed by the patient. Some patients require supplemental oxygen 24 hours a day, while others may only need treatments during exercise or sleep. No special patient preparation is required to administer oxygen therapy.

Patient education

SELECTING AN OXYGEN SYSTEM. A healthcare provider will meet with the patient to discuss the oxygen systems available. A system recommendation will be made, based on the patient's overall condition and personal needs, as well as the system's ease of use, reliability, cost, range of oxygen delivery, and features. The healthcare provider can give the patient a list of medical supply companies that stock home oxygen equipment and supplies. The patient can meet with home care representatives from these companies to evaluate the product lines that best fit his or her needs. Patients in the home setting are directed to notify the vendors when replacement oxygen supplies are needed.

OXYGEN SAFETY. Patients will receive instructions about the safe use of oxygen in the home. Patients must be advised not to change the flow rate of oxygen unless directed to do so by the physician.

Oxygen supports combustion, therefore no open flame or combustible products should be permitted when oxygen is in use. These include petroleum jelly, oils, and aerosol sprays. A spark from a cigarette, electric razor, or other electrical device could easily ignite oxygen-saturated hair or bedclothes around the patient. Explosion-proof plugs should be used for vaporizers and humidifier attachments. The patient should be sure to have a functioning smoke detector and fire extinguisher in the home at all times.

Care must be taken with oxygen equipment used in the home or hospital. The oxygen system should be kept clean and dust-free. Cylinders should be kept in carts, or have collars for safe storage. If not stored in a cart, smaller canisters may be lain on the floor. Knocking cylinders together can cause sparks, so bumping them should be avoided. In the home, the oxygen source must be placed at least 6 ft. (1.8 m) away from flames or other sources of ignition, such as a lit cigarette. Oxygen tanks should be kept in a well-ventilated area. Oxygen tanks should not be kept in the trunk of a car. "No Smoking—Oxygen in Use" signs should be used to warn visitors not to smoke near the patient.

Special care must be given when administering oxygen to premature infants because of the danger of high oxygen levels causing retinopathy of **prematurity**, or contributing to the construction of ductus arteriosus. PaO_2 (partial pressure of oxygen) levels greater than 80 mm Hg should be avoided.

Patients who are undergoing a laser **bronchoscopy** should receive concurrent administration of supplemental oxygen to avoid **burns** to the trachea.

Insurance clearance

The patient should check with his or her insurance provider to determine if the treatment is covered and what out-of-pocket expenses may be incurred. Oxygen therapy is usually fully or partially covered by most insurance plans, including Medicare, when prescribed according to specific guidelines. Usually test results indicating the medical necessity of the supplemental oxygen are needed before insurance clearance is granted.

Travel guidelines

Traveling with oxygen requires advanced planning. The patient needs to obtain a letter from his or her healthcare provider that verifies all medications, including oxygen. In addition, a copy of the patient's oxygen prescription must be shown to travel personnel. Home healthcare companies can help the patient make travel plans, and can arrange for oxygen when the patient arrives at his or her destination. Patients cannot bring or use their own oxygen tanks on an airplane; therefore the patient must leave his or her portable oxygen tank at the airport before boarding. Oxygen suppliers can pick up the oxygen unit from the airport if necessary, or a family member can take it home.

Aftercare

Once oxygen therapy is initiated, periodic assessment and documentation of oxygen saturation levels is required. Follow-up monitoring includes blood gas measurements and pulse oximetry tests. If the patient is using a mask or a cannula, gauze can be tucked under the tubing to prevent irritation of the cheeks or the skin behind the ears. Water-based lubricants can be used to relieve dryness of the lips and nostrils.

Results

A normal result is a patient that demonstrates adequate oxygenation through pulse oximetry, blood gas tests, and clinical observation. Signs and symptoms of inadequate oxygenation include **cyanosis**, drowsiness, confusion, restlessness, **anxiety**, or slow, shallow, difficult, or irregular breathing. Patients with obstructive airway disease may exhibit "aerophagia" (air hunger) as they work to pull air into the lungs. In

WWW.BOOKBAZ.IR

cases of carbon monoxide inhalation, the oxygen saturation can be falsely elevated.

Risks

Oxygen is not addictive and causes no side effects when used as prescribed. Complications from oxygen therapy used in appropriate situations are infrequent. Respiratory depression, oxygen toxicity, and absorption **atelectasis** are the most serious complications of oxygen overuse.

A physician should be notified and emergency services may be required if the following symptoms develop:

- frequent headaches
- anxiety
- cyanotic (blue) lips or fingernails
- drowsiness
- confusion
- restlessness
- slow, shallow, difficult, or irregular breathing

Oxygen delivery equipment may present other problems. Perforation of the nasal septum as a result of using a nasal cannula and nonhumidified oxygen has been reported. In addition, bacterial contamination of nebulizer and humidification systems can occur, possibly leading to the spread of **pneumonia**. High-flow systems that employ heated humidifiers and aerosol generators, especially when used by patients with artificial airways, also pose a risk of infection.

Pacemaker implantation *see* **Pacemakers**

Pacemakers

Definition

A pacemaker is a surgically implanted electronic device that regulates a slow or erratic heartbeat.

Purpose

Pacemakers are implanted to regulate irregular contractions of the heart (arrhythmia). They are most frequently prescribed to speed the heartbeat of patients who have a heart rate well under 60 beats per minute (severe symptomatic bradycardia). They are also used in some cases to slow a fast heart rate (tachycardia).

Precautions

The symptoms of **fatigue** and lightheadedness that are characteristic of bradycardia can also be caused by a number of other medical conditions, including anemia. Certain prescription medications can also slow the heart rate. A doctor should take a complete medical history and perform a full physical work-up to rule out all non-cardiac causes of bradycardia.

Patients with cardiac pacemakers should not undergo a **magnetic resonance imaging** (MRI) procedure. Devices that emit electromagnetic waves (including magnets) may alter pacemaker programming or functioning. A 1997 study found that cellular phones often interfere with pacemaker programming and cause irregular heart rhythm. However, advances in pacemaker design and materials have greatly reduced the risk of pacemaker interference from electromagnetic fields.

Description

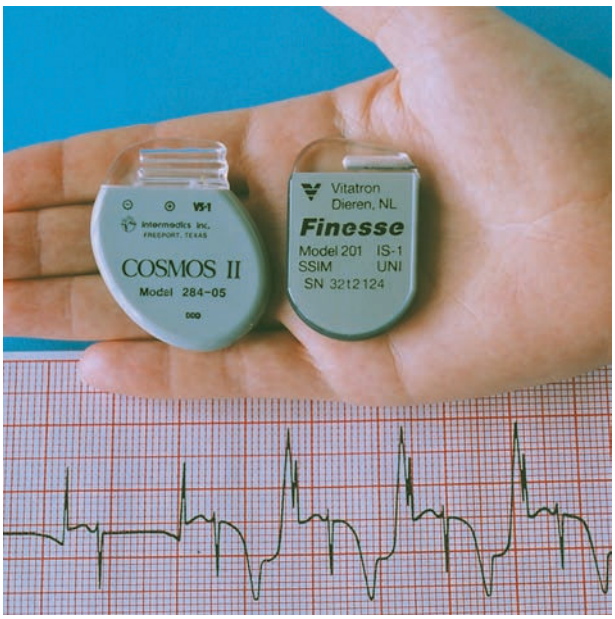
Approximately 500,000 Americans have an implantable permanent pacemaker device. A pacemaker implantation is performed under local **anesthesia** in a hospital by a surgeon assisted by a cardiologist. An insulated wire called a lead is inserted into an incision above the collarbone and guided through a large vein into the chambers of the heart. Depending on the configuration of the pacemaker and the clinical needs of the patient, as many as three leads may be used in a pacing system. Current pacemakers have a double, or bipolar, electrode attached to the end of each lead. The electrodes deliver an electrical charge to the heart to regulate heartbeat. They are positioned on the areas of the heart that require stimulation. The leads are then attached to the pacemaker device, which is implanted under the skin of the patient's chest.

Patients undergoing surgical pacemaker implantation usually stay in the hospital overnight. Once the procedure is complete, the patient's vital signs are monitored and a **chest x ray** is taken to ensure that the pacemaker and leads are properly positioned.

Modern pacemakers have sophisticated programming capabilities and are extremely compact. The smallest weigh less than 13 grams (under half an ounce) and are the size of two stacked silver dollars. The actual pacing device contains a pulse generator, circuitry programmed to monitor heart rate and deliver stimulation, and a lithiumiodide battery. Battery life typically ranges from seven to 15 years, depending on the number of leads the pacemaker is configured with and how much energy the pacemaker uses. When a new battery is required, the unit can be exchanged in a simple outpatient procedure.

A temporary pacing system is sometimes recommended for patients who are experiencing irregular heartbeats as a result of a recent **heart attack** or other acute medical condition. The implantation

WWW.BOOKBAZ.IR



Pacemakers like these are usually implanted under the skin below the collarbone. The pacemaker is connected to the heart by a wire inserted into a major vein in the neck and guided down into the heart. *(Eamonn McNulty/Photo Researchers, Inc.)*

procedure for the pacemaker leads is similar to that for a permanent pacing system, but the actual pacemaker unit housing the pulse generator remains outside the patient's body. Temporary pacing systems may be replaced with a permanent device at a later date.

Preparation

Patients being considered for pacemaker implantation will undergo a full battery of cardiac tests, including an electrocardiogram (ECG) or an electrophysiological study or both to fully evaluate the bradycardia or tachycardia.

Patients are advised to abstain from eating 6-8 hours before the surgical procedure. The patient is usually given a sedative to help him or her relax for the procedure. An intravenous (IV) line will also be inserted into a vein in the patient's arm before the procedure begins in case medication or blood products are required during the insertion.

Aftercare

Pacemaker patients should schedule a follow-up visit with their cardiologist approximately six weeks after the surgery. During this visit, the doctor will make any necessary adjustments to the settings of the pacemaker. Pacemakers are programmed externally with a handheld electromagnetic device. Pacemaker batteries must be checked regularly. Some pacing systems allow patients to monitor battery life through a special telephone monitoring service that can read pacemaker signals.

Results

Pacemakers that are properly implanted and programmed can correct a patient's arrhythmia and resolve related symptoms.

Risks

Because pacemaker implantation is an invasive surgical procedure, internal bleeding, infection, hemorrhage, and **embolism** are all possible complications. Infection is more common in patients with temporary pacing systems. Antibiotic therapy given as a precautionary measure can reduce the risk of pacemaker infection. If infection does occur, the entire pacing system may have to be removed.

The placing of the leads and electrodes during the implantation procedure also presents certain risks for the patient. The lead or electrode could perforate the heart or cause scarring or other damage. The electrodes can also cause involuntary stimulation of nearby skeletal muscles.

A complication known as *pacemaker syndrome* develops in approximately 7% of pacemaker patients with single-chamber pacing systems. The syndrome is characterized by the low blood pressure and **dizziness** that are symptomatic of bradycardia. It can usually be corrected by the implantation of a dual-chamber pacing system.

Packed red blood cell volume *see* **Hematocrit**

KEY TERMS

Electrocardiogram (ECG)—A recording of the electrical activity of the heart. An ECG uses externally attached electrodes to detect the electrical signals of the heart.

Electrophysiological study—A test that monitors the electrical activity of the heart in order to diagnose arrhythmia. An electrophysiological study measures electrical signals through a cardiac catheter that is inserted into an artery in the leg and guided up into the atrium and ventricle of the heart.

Embolism—A blood clot, air bubble, or clot of foreign material that blocks the flow of blood in an artery. When an embolism blocks the blood supply to a tissue or organ, the tissue the artery feeds dies (infarction). Without immediate and appropriate treatment, an embolism can be fatal.

Magnetic resonance imaging (MRI)—An imaging technique that uses a large circular magnet and radio waves to generate signals from atoms in the body. These signals are used to construct images of internal structures.

Paget's disease of bone

Definition

Paget's disease of bone (*osteitis deformans*) is the abnormal formation of bone tissue that results in weakened and deformed bones.

Description

Named for Sir James Paget (1814–1899), this disease affects 1–3% of people over 50 years of age, but affects over 10% of people over 80 years of age. Paget's disease can affect one or more bones in the body. Most often, the pelvis, bones in the skull, the long bones (the large bones that make up the arms and legs), and the collarbones are affected by Paget's disease. In addition, the joints between bones (the knees or elbows, for example) can develop arthritis because of this condition.

Paget's disease is characterized by changes in the normal mechanism of bone formation. Bone is a living material made by the body through the continual processes of formation and breakdown (resorption). The combination of these two actions is called remodeling and is used by the body to build bone tissue that is strong and healthy. Strong bones are formed when bone tissue is made up of plate-shaped crystals of **minerals** called hydroxyapatite. Normal wear and tear on the skeletal system is repaired throughout life by the ongoing process of remodeling. In fact, the entire human skeleton is remodeled every five years.

Healthy bone tissue has an ordered structure that gives the bone its strength. Bones affected by Paget's disease, however, have a structure that is disorganized. This disorganized structure weakens the diseased bone and makes people suffering from this disease more likely to have **fractures**. These fractures are slow to heal.

Paget's disease of bone is most commonly found in Europe, England, Australia, New Zealand, and North America. In these areas, up to 3% of all people over 55 years of age are affected with the disease. It is interesting to note that Paget's disease is rare in Asia, possibly showing that this disease may affect some ethnic groups and geographic areas more than others.

Causes and symptoms

The cause of Paget's disease is not known. Various viruses have been suggested to be involved in this disease, but the relationship between viral infections and Paget's disease remains uncertain. There also may to be a genetic component to this disease since it may appear in more than one person within the same family.

Paget's disease usually begins without any symptoms. And, in its early stages, the symptoms that do occur are often confused with symptoms of arthritis. However, as the disease progresses, bone and joint **pain** develop. A unique feature of Paget's disease is the enlargement of areas of affected bone. This type of enlargement is clearly identifiable on an x ray.

If the bones of the skull are affected by Paget's disease, enlargement of the skull can occur and may result in a loss of hearing. When the long bones in the legs are affected, they can become bent under the body's weight because of their weakness. Little or no injury to a bone can cause fractures in the weakened bones. Fractures that occur when no traumatic injury is present are known as spontaneous fractures.

WWW.BOOKBAZ.IR

This woman's legs are bowed due to Paget's disease. *(Custom Medical Stock Photo, Inc.)*

Although rare, **bone cancer** occurs in less than 1% of patients with Paget's disease. Such cancer is often accompanied by an abrupt increase in the intensity of pain at the diseased site. Unfortunately, this type of cancer has a poor prognosis; the average survival time from the onset of symptoms is generally one to three years.

Diagnosis

Paget's disease is often found when an individual is having x rays taken for medical reasons unrelated to this bone disease. A diagnosis of Paget's disease can also be made when higher than normal levels of a chemical called alkaline phosphatase are found in the blood. Alkaline phosphatase is a substance involved in the bone formation process, so if its levels are abnormally high this indicates that the balance between bone formation and resorption is upset.

Treatment

Treatment, given only when symptoms are present, consists of the following types:

Drugs

Paget's disease is most often treated with drug therapy, with bone pain lessening within weeks of starting the treatment. While nonsteroidal anti-inflammatory drugs can reduce bone pain, two additional categories of drugs are used to treat this disease.

HORMONE TREATMENT. Calcitonin, a hormone which is made naturally by the thyroid gland, is used to treat Paget's disease. This chemical rapidly decreases the amount of bone breakdown or loss (resorption). After approximately two to three weeks of treatment with extra calcitonin, bone pain lessens and new bone tissue forms. Calcitonin is commonly given as daily injections for one month, followed by three injections each week for several additional months. The total dose of calcitonin given to an individual depends upon the amount of disease present and how well the individual's condition responds to the treatment.

Although calcitonin is effective in slowing the progression of Paget's disease, the favorable effects of the drug do not continue for very long once administration of the drug is stopped. In addition, some temporary side effects can occur with this drug. Nausea and flushing are the most common side effects and have been found in 20–30% of individuals taking calcitonin. **Vomiting**, **diarrhea**, and abdominal pain can also occur, but these effects are also temporary. A form of calcitonin taken nasally causes fewer side effects, but requires higher doses because less of the drug reaches the diseased bone.

BISPHOSPHONATES. The bisphosphonate group of drugs are drugs that bind directly to bone minerals because of their specific chemical structure. Once bound to the bone, these drugs inhibit bone loss by reducing the action of bone cells that normally degrade bone during the remodeling process. Unlike treatment with calcitonin, the positive effects of increased bone formation and reduced pain can continue for many months or even years after bisphosphonate treatment is stopped. Bisphosphonates are considered the treatment of choice for Paget's disease and are usually given for three to six months at a time.

Bisphosphonate drugs suitable for the treatment of Paget's disease are alendronate, clodronate, etidronate,

KEY TERMS

Bisphosphonate—A class of drugs used to treat Paget's disease. These drugs bind to the minerals in bone tissue and lessen the amount of bone loss associated with Paget's disease.

Calcitonin—A naturally occurring hormone made by the thyroid gland that can be used as a drug to treat Paget's disease.

Remodeling—The ongoing process of bone formation and breakdown that results in healthy bone development.

pamidronate, risedronate, and tiludronate. The main side effects of these drugs include a flu-like reaction (pamidronate), gastrointestinal disturbances (alendronate, clodronate), and abnormal bone formation (etidronate, when taken in high doses). Risedronate is the newest of these drugs. It is about 1,000 times more potent than etidronate and three to five times more potent than alendronate. Because of the greater potency of this drug, lower doses and a shorter duration of treatment are required. This leads to fewer side effects with similar, or better, clinical results in the patient.

Surgery

Treatment of Paget's disease usually begins with drug therapy. However, various surgical treatments can also be used to treat skeletal conditions that occur in patients with Paget's disease.

In patients with severe arthritis of the hip or knee, a joint replacement operation can be beneficial. However, in addition to the malformation of bone tissue caused by this condition, there are greater numbers of blood vessels that form in the diseased bone relative to a healthy bone. This makes surgery on bones affected with Paget's disease more difficult.

Prognosis

There is no cure for Paget's disease. However, the development of potent bisphosphonate drugs like risedronate has resulted in the ability to slow the progress of the disease.

Paul A. Johnson, EdM

Paget's disease of the breast

Definition

Paget's disease of the breast is a rare form of **breast cancer** which makes up approximately 1–4 % of all breast tumors. While sharing its name with Paget's disease of bone, these are two medically unrelated conditions. They are simply named after the same doctor who first described them.

Description

Paget's disease of the breast is generally associated with an underlying breast cancer. It is generally seen in people between the ages of 40 and 80 years. Cases in men have been identified, but they are extremely rare.

Paget's disease of the breast may also be called mammary Paget's disease (MPD). There is a much rarer form of this disease called extramammary Paget's disease (EMPD). MPD affects the breast nipple and is also called Paget's disease of the nipple. EMPD can affect the skin of the external genital tissues in both women and men, as well as the skin of the eyelids and external ear canal. MPD is believed to develop from a tumor growth within the milk ducts of the breast. EMPD may represent a spreading (metastasis) of MPD to other parts of the body.

Causes and symptoms

The cause of Paget's disease of the breast is unknown, but it is usually associated with an underlying cancer of the breast.

The symptoms of Paget's disease of the breast include:

- red scaly patches of skin on the nipple and sometimes also on the dark area of skin around the nipple (areola)
- crusting, bleeding, or ulceration of the skin of the affected area
- a discharge of fluid from the nipple
- a turning inward (inversion) of the nipple

In approximately 30–40% of cases of Paget's disease of the breast, there is also a detectable lump in the breast.

Diagnosis

Paget's disease of the breast is often confused with other skin conditions, such as **eczema**, **dermatitis**, or

WWW.BOOKBAZ.IR

psoriasis. These misdiagnoses often lead to delays in appropriate treatment. Misdiagnosis is more common when both breast are affected and no lump in the breast is detected. When only one breast is affected, or when the presence of a lump in the breast is also detected, a correct initial diagnosis is more likely to occur.

Once Paget's disease of the breast is suspected, it can be definitively confirmed by biopsy of the affected tissue. In this procedure, a small piece of the affected skin and the underlying tissue is removed and sent to a laboratory for examination under a microscope. The shape and other characteristics of the cells in the biopsied sample will allow the laboratory personnel to determine if the sample is affected with Paget's disease of the breast, or some other condition.

Topical steroid creams are usually used to treat eczema, dermatitis, and psoriasis. These creams will have no effect on the skin conditions caused by Paget's disease of the breast.

Treatment

Surgery is the main treatment for Paget's disease of the breast. Removal of the breast (**mastectomy**) may be recommended if the cancer is seen in a wide area away from the nipple or appears to be deep into the breast tissue. Breast conservation surgery, aimed at keeping as much of the breast as possible, may be recommended in cases where the disease is diagnosed early enough and the cancer has not spread far from the surface of the nipple.

Some people will require further treatment after surgery. This treatment may include **radiation therapy**, **chemotherapy**, or a combination of both. Radiation therapy involves using high-energy x rays to destroy any cancer cells that may remain after surgical removal of the primary tumor. Radiation therapy is most common after breast conservation surgery. Chemotherapy involves the use of medicinal drugs to destroy the growth of any cancer cells that may remain after removal of the primary cancer. Chemotherapy treatments are most common after mastectomy.

Alternatives

Alternative treatments for Paget's disease of the breast include: the use of cartilage from cows or sharks; a diet known as Gerson therapy; administration of the chemicals hydrazine sulfate or laetrile; and, the injection of solutions derived from the mistletoe plant.

KEY TERMS

Metastasis—The spread of a cancer from one part of the body (where the cancer originated) to another part of the body.

Ulceration—The formation of an ulcer, a patch of tissue that is discontinuous with the surrounding tissue because the tissue within the ulcer has decayed or died and been swept away.

Prognosis

The prognosis for Paget's disease of the breast depends on the underlying cancer that is causing this condition and whether or not this cancer has spread (metastasized) to other parts of the body.

Prevention

Because the cause of Paget's disease of the breast is not known, prevention of this disease is not possible. In instances where this conditions arises from other underlying cancers of the breast, it may be possible to prevent Paget's disease of the breast from occurring if the underlying cause is diagnosed and successfully treated prior to the development of Paget's disease of the breast.

Pain

Definition

Pain is an unpleasant feeling that is conveyed to the brain by sensory neurons. The discomfort signals actual or potential injury to the body. However, pain is more than a sensation, or the physical awareness of pain; it also includes perception, the subjective interpretation of the discomfort. Perception gives information on the pain's location, intensity, and something about its nature. The various conscious and unconscious responses to both sensation and perception, including the emotional response, add further definition to the overall concept of pain.

Description

Pain arises from any number of situations. Injury is a major cause, but pain may also arise from an illness. It may accompany a psychological condition, such as depression, or may even occur in the absence of a recognizable trigger.

Acute pain

Acute pain often results from tissue damage, such as a skin burn or broken bone. Acute pain can also be associated with headaches or **muscle cramps**. This type of pain usually goes away as the injury heals or the cause of the pain (stimulus) is removed.

To understand acute pain, it is necessary to understand the nerves that support it. Nerve cells, or neurons, perform many functions in the body. Although their general purpose, providing an interface between the brain and the body, remain constant, their capabilities vary widely. Certain types of neurons are capable of transmitting a pain signal to the brain.

As a group, these pain-sensing neurons are called nociceptors, and virtually every surface and organ of the body is wired with them. The central part of these cells is located in the spine, and they send threadlike projections to every part of the body. Nociceptors are classified according to the stimulus that prompts them to transmit a pain signal. Thermoreceptive nociceptors are stimulated by temperatures that are potentially tissue damaging. Mechanoreceptive nociceptors respond to a pressure stimulus that may cause injury. Polymodal nociceptors are the most sensitive and can respond to temperature and pressure. Polymodal nociceptors also respond to chemicals released by the cells in the area from which the pain originates.

Nerve cell endings, or receptors, are at the front end of pain sensation. A stimulus at this part of the nociceptor unleashes a cascade of neurotransmitters (chemicals that transmit information within the nervous system) in the spine. Each neurotransmitter has a purpose. For example, substance P relays the pain message to nerves leading to the spinal cord and brain. These neurotransmitters may also stimulate nerves leading back to the site of the injury. This response prompts cells in the injured area to release chemicals that not only trigger an immune response, but also influence the intensity and duration of the pain.

Chronic and abnormal pain

Chronic pain refers to pain that persists after an injury heals, cancer pain, pain related to a persistent or degenerative disease, and long-term pain from an unidentifiable cause. It is estimated that one in three people in the United States will experience chronic pain at some point in their lives. Of these people, approximately 50 million are either partially or completely disabled.

Chronic pain may be caused by the body's response to acute pain. In the presence of continued stimulation of nociceptors, changes occur within the nervous system. Changes at the molecular level are dramatic and may include alterations in genetic transcription of neurotransmitters and receptors. These changes may also occur in the absence of an identifiable cause; one of the frustrating aspects of chronic pain is that the stimulus may be unknown. For example, the stimulus cannot be identified in as many as 85% of individuals suffering lower back pain.

Scientists have long recognized a relationship between depression and chronic pain. In 2004, a survey of California adults diagnosed with major depressive disorder revealed that more than one-half of them also suffered from chronic pain.

Other types of abnormal pain include allodynia, hyperalgesia, and phantom limb pain. These types of pain often arise from some damage to the nervous system (neuropathic). Allodynia refers to a feeling of pain in response to a normally harmless stimulus. For example, some individuals who have suffered nerve damage as a result of viral infection experience unbearable pain from just the light weight of their clothing. Hyperalgesia is somewhat related to allodynia in that the response to a painful stimulus is extreme. In this case, a mild pain stimulus, such as a pin prick, causes a maximum pain response. Phantom limb pain occurs after a limb is amputated; although an individual may be missing the limb, the nervous system continues to perceive pain originating from the area.

WWW.BOOKBAZ.IR

Causes and symptoms

Pain is the most common symptom of injury and disease, and descriptions can range in intensity from a mere ache to unbearable agony. Nociceptors have the ability to convey information to the brain that indicates the location, nature, and intensity of the pain. For example, stepping on a nail sends an information-packed message to the brain: the foot has experienced a puncture wound that hurts a lot.

Pain perception also varies depending on the location of the pain. The kinds of stimuli that cause a pain response on the skin include pricking, cutting, crushing, burning, and freezing. These same stimuli would not generate much of a response in the intestine. Intestinal pain arises from stimuli such as swelling, inflammation, and distension.

Diagnosis

Pain is considered in view of other symptoms and individual experiences. An observable injury, such as a broken bone, may be a clear indicator of the type of pain a person is suffering. Determining the specific cause of internal pain is more difficult. Other symptoms, such as **fever** or nausea, help narrow down the possibilities. In some cases, such as lower back pain, a specific cause may not be identifiable. Diagnosis of the disease causing a specific pain is further complicated by the fact that pain can be referred to (felt at) a skin site that does not seem to be connected to the site of the pain's origin. For example, pain arising from fluid accumulating at the base of the lung may be referred to the shoulder.

Since pain is a subjective experience, it may be very difficult to communicate its exact quality and intensity to other people. There are no diagnostic tests that can determine the quality or intensity of an individual's pain. Therefore, a medical examination will include a lot of questions about where the pain is located, its intensity, and its nature. Questions are also directed at what kinds of things increase or relieve the pain, how long it has lasted, and whether there are any variations in it. An individual may be asked to use a pain scale to describe the pain. One such scale assigns a number to the pain intensity; for example, 0 may indicate no pain, and 10 may indicate the worst pain the person has ever experienced. Scales are modified for infants and children to accommodate their level of comprehension.

Treatment

There are many drugs aimed at preventing or treating pain. Nonopioid **analgesics**, narcotic analgesics, **anticonvulsant drugs**, and tricyclic antidepressants work by blocking the production, release, or uptake of neurotransmitters. Drugs from different classes may be combined to handle certain types of pain.

Nonopioid analgesics include common over-the-counter medications such as **aspirin**, **acetaminophen** (Tylenol), and ibuprofen (Advil). These are most often used for minor pain, but there are some prescription-strength medications in this class.

Narcotic analgesics are only available with a doctor's prescription and are used for more severe pain, such as cancer pain. These drugs include codeine, morphine, and **methadone**. **Addiction** to these painkillers is not as common as once thought. Many people who genuinely need these drugs for pain control typically do not become addicted. However, narcotic use is usually limited to patients thought to have a short life span (such as people with terminal cancer) or patients whose pain is only expected to last for a short time (such as people recovering from surgery). In 2004, the Drug Enforcement Administration (DEA) issued new guidelines to help physicians prescribe **narcotics** appropriately without fear of being arrested for prescribing the drugs beyond the scope of their medical practice. DEA is trying to work with physicians to ensure that those who need to drugs receive them but to ensure opioids are not abused.

Anticonvulsants, as well as **antidepressant drugs**, were initially developed to treat seizures and depression, respectively. However, it was discovered that these drugs also have pain-killing applications. Furthermore, since in cases of chronic or extreme pain, it is not unusual for an individual to suffer some degree of depression; antidepressants may serve a dual role. Commonly prescribed anticonvulsants for pain include phenytoin, carbamazepine, and clonazepam. Tricyclic antidepressants include doxepin, amitriptyline, and imipramine.

Intractable (unrelenting) pain may be treated by injections directly into or near the nerve that is transmitting the pain signal. These root blocks may also be useful in determining the site of pain generation. As the underlying mechanisms of abnormal pain are uncovered, other pain medications are being developed.

Drugs are not always effective in controlling pain. Surgical methods are used as a last resort if drugs and local anesthetics fail. The least destructive surgical procedure involves implanting a device that emits electrical signals. These signals disrupt the nerve and prevent it from transmitting the pain message. However, this method may not completely control pain and is not used frequently. Other surgical techniques involve

destroying or severing the nerve, but the use of this technique is limited by side effects, including unpleasant numbness.

Two effective **pain management** treatments that have been used for generations are heat and cold. Both are used to treat acute and chronic pain. Ice is generally used to treat inflammation, especially acute injuries to knees and other joints. Treatment usually lasts three to five days. Often it is used as part of the RICE regimen: rest, ice, compression, and elevation. Heat therapy is generally used for increasing tensile strength, increasing blood flow to the injured area, and helping muscles and tendons to relax. Sometimes ice is used in the early stages of an acute injury and then heat for the remainder of treatment. In recent years, scientists have identified heat and cold receptors in the body. This has allowed the development of medications, including patches, creams, and gels, that directly target these receptors, increasing the effectiveness of heat and cold treatments.

Alternatives

Both physical and psychological aspects of pain can be dealt with through alternative treatment. Some of the most popular treatment options include **acupressure** and **acupuncture**, massage, **chiropractic**, and relaxation techniques such as **yoga**, hypnosis, and **meditation**. Herbal therapies are gaining increased recognition as viable options; for example, capsaicin, the component that makes cayenne peppers spicy, is used in ointments to relieve the joint pain associated with arthritis. Contrast **hydrotherapy** can also be very beneficial for pain relief.

Lifestyles can be changed to incorporate a healthier diet and regular **exercise**. Regular exercise, aside from relieving **stress**, has been shown to increase endorphins, painkillers naturally produced in the body.

Prognosis

Successful pain treatment is highly dependent on successful resolution of the pain's cause. Acute pain will stop when an injury heals or when an underlying problem is treated successfully. Chronic pain and abnormal pain are more difficult to treat, and it may take longer to find a successful resolution. Some pain is intractable and will require extreme measures for relief.

Prevention

Pain is generally preventable only to the degree that the cause of the pain is preventable. For example, improved surgical procedures, such as those done through a thin tube called a laparascope, minimize post-operative pain. **Anesthesia** techniques for surgeries also continuously improve. Some disease and injuries are often unavoidable. However, pain from some surgeries and other medical procedures and continuing pain are preventable through drug treatments and alternative therapies.

KEY TERMS

Acute pain—Pain in response to injury or another stimulus that resolves when the injury heals or the stimulus is removed.

Chronic pain—Pain that lasts beyond the term of an injury or painful stimulus. Can also refer to cancer pain, pain from a chronic or degenerative disease, and pain from an unidentified cause.

Neuron—A nerve cell.

Neurotransmitters—Chemicals within the nervous system that transmit information from or between nerve cells.

Nociceptor—A neuron that is capable of sensing pain.

Referred pain—Pain felt at a site different from the location of the injured or diseased part of the body. Referred pain is due to the fact that nerve signals from several areas of the body may "feed" the same nerve pathway leading to the spinal cord and brain.

Stimulus—A factor capable of eliciting a response in a nerve.

Pain management

Definition

Pain itself is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage." Thus, pain management encompasses all interventions used to understand and ease pain, and if possible to alleviate the cause of the pain.

Purpose

Pain serves to alert a person to potential or actual damage to the body. The definition of damage is quite broad: pain can arise from injury as well as disease. After the message is received and interpreted, further pain can be counterproductive. Pain can have a negative impact on a person's quality of life and impede recovery from illness or injury, thus contributing to escalating healthcare costs. Unrelieved pain can become a syndrome in its own right and cause a downward spiral in a person's health and emotional outlook. Managing pain properly facilitates recovery, prevents additional health complications, and improves an individual's quality of life.

Yet the experiencing of pain is a completely unique occurrence for each person, a complex combination of several factors other than the pain itself. It is influenced by:

- Ethnic and cultural values. In some cultures, tolerating pain is related to showing strength and endurance. In others, pain is considered punishment for misdeeds.
- Age. Many people have been taught that grownups never cry. On the other hand, in some cultures, the elderly are allowed to complain freely about pain and discomfort.
- Anxiety and stress. This factor is related to being in a strange or unfamiliar place such as a hospital, and the fear of the unknown consequences of the pain and the condition causing it, which can all combined to make pain feel more severe. For patients being treated for pain, knowing the duration of activity of an analgesic leads to anxiety about the return of pain when the drug wears off. This anxiety can make the pain more severe. In addition, patients who interpret their pain as meaning that their disease is recurring or getting worse often experience pain as more severe.
- Fatigue and depression. It is known that pain in itself can actually cause emotional depression. Fatigue from lack of sleep or the illness itself also contributes to depressed feelings.

Precautions

The perception of pain is an individual experience. Healthcare providers play an important role in understanding their patients' pain. All too often, both physicians and nurses have been found to incorrectly assess the severity of pain. A study reported in the *Journal of Advanced Nursing* evaluated nurses' perceptions of a select group of white American and Hispanic American women patients' pain following gallbladder surgery. Objective assessments of each patient's pain showed little difference between the perceived severities for each group. Yet, the nurses involved in the study consistently rated all patients' pain as less than the patients reported, and with equal consistency, believed that better-educated women born in the United States were suffering more than less-educated Hispanic American women. Nurses from a northern European background were more apt to minimize the severity of pain than nurses from eastern and southern Europe or Africa. The study indicated how healthcare staff, and especially nursing staff, need to be aware of how their own background and experience contributes to how they perceive a person's pain.

Some patient populations are particularly susceptible to inadequate pain management. These include cancer patients; children; **trauma** victims receiving treatment in hospital emergency departments; and the elderly in nursing homes.

KEY TERMS

Acute—Referring to pain in response to injury or other stimulus that resolves when the injury heals or the stimulus is removed.

Central nervous system (CNS)—The part of the nervous system that includes the brain and the spinal cord.

Chronic—Referring to pain that endures beyond the term of an injury or painful stimulus. Can also refer to cancer pain, pain from a chronic or degenerative disease, and pain from an unidentified cause.

Iatrogenic—Resulting from the activity of the physician.

Neuropathy—Nerve damage.

Neurotransmitter—Chemicals within the nervous system that transmit information from or between nerve cells.

Nociceptor—A nerve cell that is capable of sensing pain and transmitting a pain signal.

Nonpharmacological—Referring to therapy that does not involve drugs.

Parasympathetic nervous system—That part of the autonomic nervous system consisting of nerves that arise from the cranial and sacral regions and function in opposition to the sympathetic nervous system.

Peripheral nervous system (PNS)—Nerves that are outside of the brain and spinal cord.

Pharmacological—Referring to therapy that relies on drugs.

Stimulus—A factor capable of eliciting a response in a nerve.

Sympathetic nervous system—That portion of the autonomic nervous system consisting of nerves that originate in the thoracic and lumbar spinal cord and function in opposition to the parasympathetic nervous system.

Description

Before considering pain management, a review of pain definitions and mechanisms may be useful. Pain is the means by which the peripheral nervous system (PNS) warns the central nervous system (CNS) of injury or potential injury to the body. The CNS comprises the brain and spinal cord, and the PNS is composed of the nerves that stem from and lead into the CNS. PNS includes all nerves throughout the body, except the brain and spinal cord. Pain is sometimes categorized by its site of origin, either cutaneous (originating in the skin, or subcutaneous tissue, such as a shaving nick or paper cut), deep somatic pain (arising from bone, ligaments and tendons, nerves, or veins and arteries), or visceral (appearing as a result of stimulation of pain receptor nerves around such organs as the brain, lungs, or stomach and intestines).

A pain message is transmitted to the CNS by special PNS nerve cells called nociceptors, which are distributed throughout the body and respond to different stimuli depending on their location. For example, nociceptors that extend from the skin are stimulated by such sensations as pressure, temperature, and chemical changes.

When a nociceptor is stimulated, neurotransmitters are released within the cell. Neurotransmitters are chemicals found within the nervous system that facilitate nerve cell communication. The nociceptor transmits its signal to nerve cells within the spinal cord, which conveys the pain message to the thalamus, a specific region in the brain.

Once the brain has received and processed the pain message and coordinated an appropriate response, pain has served its purpose. The body uses natural painkillers called endorphins to derail further pain messages from the same source. However, these natural painkillers may not adequately dampen a continuing pain message. Also, depending on how the brain has processed the pain information, certain hormones such as prostaglandins may be released. These hormones enhance the pain message and play a role in immune system responses to injury, such as inflammation. Certain neurotransmitters, especially substance P and calcitonin gene-related peptide, actively enhance the pain message at the injury site and within the spinal cord.

Pain is generally divided into two additional categories: acute and chronic. Nociceptive pain, or the pain that is transmitted by nociceptors, is typically called acute pain. This kind of pain is associated with injury, headaches, disease, and many other conditions. Response to acute pain is made by the sympathetic nervous system (the nerves responsible for the fight-or-flight response of the body). It normally resolves once the condition that precipitated it is resolved.

There are some disorders that produce pain that does not resolve following the disorder. Even after healing or a cure has been achieved, the brain continues to perceive pain. In this situation, the pain may be considered chronic. Chronic pain is within the province of the parasympathetic nervous system, and the

WWW.BOOKBAZ.IR

changeover occurs as the body attempts to adapt to the pain. The time limit used to define chronic pain typically ranges from three to six months, although some healthcare professionals prefer a more flexible definition and consider chronic pain as pain that endures beyond a normal healing time. The pain associated with cancer, persistent and degenerative conditions, and neuropathy, or nerve damage, is included in the chronic category. Also, unremitting pain that lacks an identifiable physical cause such as the majority of cases of **low back pain** may be considered chronic. The underlying **biochemistry** of chronic pain appears to be different from that of acute nociceptive pain.

It has been hypothesized that uninterrupted and unrelenting pain can induce changes in the spinal cord. In the past, severing a nerve's connection to the CNS has treated intractable pain. However, the lack of any sensory information being relayed by that nerve can cause pain transmission in the spinal cord to go into overdrive, as evidenced by the phantom limb pain experienced by amputees. Evidence is accumulating that unrelenting pain or the complete lack of nerve signals increases the number of pain receptors in the spinal cord. Nerve cells in the spinal cord may also begin secreting pain-amplifying neurotransmitters independent of actual pain signals from the body. Immune chemicals, primarily cytokines, may play a prominent role in such changes.

Managing pain

Considering the different causes and types of pain, as well as its nature and intensity, management usually requires a multidisciplinary approach. The elements of this approach include treating the underlying cause of pain, pharmacological and nonpharmacological therapies, and some invasive (surgical) procedures.

Treating the cause of pain underlies the basic strategy of pain management. Injuries are repaired, diseases are diagnosed, and certain encounters with pain can be anticipated and treated prophylactically (by prevention). However, there are no guarantees of immediate relief from pain. Recovery can be impeded by pain and quality of life can be damaged. Therefore, pharmacological and other therapies have developed over time to address these aspects of disease and injury.

PHARMACOLOGICAL OPTIONS. General guidelines developed by the World Health Organization (WHO) have been developed for pain management. These guidelines operate upon the three-step ladder approach, including:

- Mild pain is alleviated with acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID). NSAIDs and acetaminophen are available as over-the-counter (OTC) and prescription medications, and are frequently the initial pharmacological treatment for pain. These drugs can also be used as adjuncts to the other drug therapies that might require a doctor's prescription. NSAIDs include aspirin, ibuprofen (Motrin, Advil, Nuprin), naproxen sodium (Aleve), and ketoprofen (Orudis KT). These drugs are used to treat pain from inflammation and work by blocking production of pain-enhancing neurotransmitters. Acetaminophen is also effective against pain, but its ability to reduce inflammation is limited. NSAIDs and acetaminophen are effective for most forms of acute (sharp, but of a short duration) pain.
- Mild to moderate pain is eased with a milder opioid medication, plus acetaminophen or NSAIDs. Opioids include both drugs derived from the opium poppy, such as morphine and codeine, and synthetic drugs based on the structure of opium. This drug class includes drugs such as oxycodone, methadone, and meperidine (Demerol). They provide pain relief by binding to specific opioid receptors in the brain and spinal cord. One drawback of opioids, however, is that they frequently cause constipation because they slow down the rhythmic muscular contractions of the intestines that push food along during the process of digestion.
- Moderate to severe pain is treated with stronger opioid drugs, plus acetaminophen or NSAIDs. Morphine is sometimes referred to as the gold standard of palliative care as it is not expensive; can be given by starting with smaller doses and gradually increased; and is highly effective over a long period of time. It can also be given by a number of different routes, including by mouth, rectally, or by injection.

Although **antidepressant drugs** were developed to treat depression, it has been discovered that they are also effective in combating chronic headaches, cancer pain, and pain associated with nerve damage. Antidepressants that have been shown to have analgesic (pain-reducing) properties include amitriptyline (Elavil), trazodone (Desyrel), and imipramine (Tofranil). **Anticonvulsant drugs** share a similar background with antidepressants. Developed to treat **epilepsy**, anticonvulsants were found to relieve pain as well. Drugs such as phenytoin (Dilantin) and carbamazepine (Tegretol) are prescribed to treat the pain associated with nerve damage.

In some cases, chronic pain caused by complications of diabetes or cancer can be eased by administering local anesthetics. The most commonly used are mexiletine (Mexitil) and a lidocaine patch.

Corticosteroids are another class of drugs commonly given to manage chronic pain caused by arthritis or other diseases affecting the muscles and joints; they may also be given to control nausea. Dexamethasone (Decadron) and prednisone are the most commonly used corticosteroids in pain management. They work by reducing inflammation and suppressing the immune system.

Close monitoring of the effects of pain medications is required in order to assure that adequate amounts of medication are given to produce the desired pain relief. When a person is comfortable with a certain dosage of medication, oncologists typically convert to a long-acting version of that medication. Transdermal fentanyl patches (Duragesic) are a common example of a long-acting opioid drug often used for cancer pain management. A patch containing the drug is applied to the skin and continues to deliver the drug to the person for an average of three days. Pumps are also available that provide an opioid medication upon demand when the person is experiencing pain. By pressing a button, they can release a set dose of medication into an intravenous solution or an implanted catheter. Another mode of administration involves implanted catheters that deliver pain medication directly to the spinal cord. Because these pumps offer the patient some degree of control over the amount of analgesic administered, the system, commonly called patient-controlled analgesia (PCA), reduces the level of **anxiety** about availability of pain medication. Delivering drugs in this way can reduce side effects and increase the effectiveness of the drug. Research is underway to develop toxic substances that act selectively on nerve cells that carry pain messages to the brain. These substances would kill the selected cells and stop transmission of the pain message.

NONPHARMACOLOGICAL OPTIONS. Pain treatment options that do not use drugs are often used as adjuncts to, rather than replacements for, drug therapy. One of the benefits of nondrug therapies is that an individual can take a more active role in pain management. Such relaxation techniques as **yoga** and **meditation** are used to focus the brain elsewhere than on the pain, decrease muscle tension, and reduce **stress**. Tension and stress can also be reduced through **biofeedback**, in which an individual consciously attempts to modify skin temperature, muscle tension, blood pressure, and heart rate.

Hypnosis is another nonpharmacological option for pain relief. Although doctors do not yet fully understand how hypnosis works, it is used successfully in some patients to manage pain related to **childbirth**, oral surgery, burn treatment, and other procedures that require the patient to remain conscious.

Participating in normal activities and exercising can also help control pain levels. Through **physical therapy**, an individual learns beneficial exercises for reducing stress, strengthening muscles, and staying fit. Regular **exercise** has been linked to production of endorphins, the body's natural painkillers.

Acupuncture involves the insertion of small needles into the skin at key points. **Acupressure** uses these same key points, but involves applying pressure rather than inserting needles. Both of these methods may work by prompting the body to release endorphins. Applying heat or being massaged are very relaxing and help reduce stress. Transcutaneous **electrical nerve stimulation** (TENS) applies a small electric current to certain parts of nerves, potentially interrupting pain signals and inducing release of endorphins. To be effective, use of TENS should be medically supervised.

INVASIVE PROCEDURES. There are three types of invasive procedures that may be used to manage or treat pain: anatomic, augmentative, and ablative. These procedures involve surgery, and certain guidelines should be followed before carrying out a procedure with permanent effects. First, the cause of the pain must be clearly identified. Next, surgery should be done only if noninvasive procedures are ineffective. Third, any psychological issues should be addressed. Finally, there should be a reasonable expectation of success.

Anatomic procedures involve correcting the injury or removing the cause of pain. Relatively common anatomic procedures are decompression surgeries such as repairing a **herniated disk** in the lower back or relieving the nerve compression related to **carpal tunnel syndrome**. Another anatomic procedure is neurolysis, also called a nerve block, which involves destroying a portion of a peripheral nerve.

Augmentative procedures include electrical stimulation or direct application of drugs to the nerves that are transmitting the pain signals. Electrical stimulation works on the same principle as TENS. In this procedure, instead of applying the current across the skin, electrodes are implanted to stimulate peripheral nerves or nerves in the spinal cord. Augmentative procedures also include implanted drug-delivery systems. In these systems, catheters are implanted in the spine to allow direct delivery of drugs to the CNS.

Ablative procedures are characterized by severing a nerve and disconnecting it from the CNS. However, this method may not address potential alterations within the spinal cord. These changes perpetuate

WWW.BOOKBAZ.IR

pain messages and do not cease, even when the connection between the sensory nerve and the CNS is severed. With growing understanding of neuropathic pain and development of less invasive procedures, ablative procedures are used less frequently. However, they do have applications in select cases of **peripheral neuropathy**, cancer pain, and other disorders.

Preparation

Prior to beginning management, the patient's pain should be thoroughly evaluated, including a psychosocial as well as a physical assessment. Pain scales or questionnaires can be administered by a member of the healthcare team, although there is no single questionnaire that is universally accepted. Some questionnaires are verbal, while others use pictures or drawings to help the patient describe the pain. Some questionnaires are filled out by the patient, while others may be given to relatives or friends to complete. It is often necessary to ask other family members to complete a pain questionnaire if the patient is cognitively impaired.

In spite of their limitations, questionnaires and self-report forms do allow healthcare workers to better understand the pain being suffered by the patient. Evaluation also includes physical examinations and diagnostic tests to determine the underlying physical causes of the pain. Some evaluations require assessments from several viewpoints, including neurology, psychiatry and psychology, and physical therapy. If the pain is caused by a medical procedure, management consists of anticipating the type and intensity of associated pain and managing it preemptively.

Nurses or physicians often take what is called a pain history. This history will help to provide important information that can help healthcare providers to better manage the patient's pain. A typical pain history includes the following questions:

- Where is the pain located?
- On a scale of 1 to 10, with 1 indicating the least pain, how would the person rate the pain being experienced?
- What does the pain feel like?
- When did (or does) the pain start?
- How long has the person had it?
- Is the person sometimes free of pain?
- Is the pain constant, or is it episodic?
- Does the person know of anything that triggers the pain or makes it worse?
- Does the person have other symptoms (nausea, dizziness, blurred vision, etc.) during or after the pain?
- What pain medications or other measures has the person found to help in easing the pain?
- How does the pain affect the person's ability to carry on normal activities?
- What does it mean to the person that he or she is experiencing pain?

Aftercare

An assessment by nursing staff as well as other healthcare providers should be made to determine the effectiveness of the pain management interventions employed. There are objective, measurable signs and symptoms of pain that can be looked for. The goal of good pain management is the absence of these signs. Signs of acute pain include:

- rise in pulse and blood pressure
- more rapid breathing
- perspiring profusely, clammy skin
- taut muscles
- more tense appearance, fast speech, very alert
- unusually pale skin
- dilated pupils of the eye

Signs of chronic pain include:

- lower pulse and blood pressure
- changeable breathing pattern
- warm, dry skin
- nausea and vomiting
- slow or monotone speech
- inability or difficulty in getting out of bed and performing activities of daily living (ADLs)
- constricted pupils of the eye

When these signs are absent and the patient appears to be comfortable, healthcare providers can consider their interventions to have been successful. It is also important to document interventions used, and which ones were successful.

Results

Effective application of pain management techniques reduces or eliminates acute or chronic pain. This treatment can improve an individual's quality of life and aid in recovery from injury and disease.

Risks

Owing to toxicity over the long term, some drugs can only be used for acute pain or as

adjuncts in chronic pain management. NSAIDs have the well-known side effect of causing gastrointestinal bleeding, and long-term use of **acetaminophen** has been linked to kidney and liver damage. Other drugs, especially **narcotics**, have such serious side effects as **constipation**, drowsiness, and nausea. Serious side effects can also accompany pharmacological therapies; mood swings, confusion, bone thinning, cataract formation, increased blood pressure, and other problems may discourage or prevent use of some **analgesics**.

Nonpharmacological therapies carry little or no risks. However, individuals recovering from serious illness or injury should consult with the healthcare providers or physical therapists before making use of adjunct therapies. Invasive procedures carry risks similar to other surgical procedures, such as infection, reaction to **anesthesia**, and iatrogenic (injury as a result of treatment) injury.

A traditional concern about narcotics use has been the risk of promoting **addiction**. As narcotic use continues over time, the body becomes accustomed to the drug and adjusts normal functions to accommodate to its presence. Therefore, to elicit the same level of action, it is necessary to increase dosage over time. As dosage increases, an individual may become physically dependent on narcotic drugs.

However, physical dependence is different from psychological addiction. Physical dependence is characterized by discomfort if drug administration suddenly stops, while psychological addiction is characterized by an overpowering craving for the drug for reasons other than pain relief. Psychological addiction is a very real and necessary concern in some instances, but it should not interfere with a genuine need for narcotic pain relief. However, caution must be taken with people who have a history of addictive behavior.

Paleo diet

Definition

The Paleo diet is an eating plan that is intended to mimic as closely as possible the way that the ancestors of humans ate more than 10,000 years ago. It is also known as the Paleolithic or caveman diet. Supporters

WWW.BOOKBAZ.IR

of this eating plan maintain that Paleolithic people did not suffer from contemporary conditions such as **heart disease**, cancer, and diabetes; others point out, however, that Paleolithic people had a much shorter lifespan than humans today and so did not live long enough to develop these conditions.

Description

Origins

The Paleolithic period, also known as the Old Stone Age, began about two million years ago. It ended at various times around the world, concluding about 10,000 years ago in Europe and the Middle East. The period is associated historically with modern humans, and the era is the basis of the modern Paleolithic diet.

During the Paleolithic period, the ancestors of humans were hunters and gatherers who lived in primitive shelters such as caves. They ate the foods that they found in the wild, hunting for animals that they killed for meat and gathering foods like fruits and vegetables. Though milk and other dairy products were not yet available (because animals had not yet been domesticated), mothers did breastfeed their babies.

During the Neolithic period (New Stone Age) that followed, people formed villages and started to domesticate plants and animals. They used fire to cook food and began farming. The first crops included grains, leading to the increased consumption of grain-based foods. These post-Paleolithic foods are generally not allowed on Paleo **diets**.

Paleolithic **nutrition** was the subject of a 1985 *New England Journal of Medicine* article by S. Boyd Eaton and Melvin Konner, whom some people regard as the founders of the modern Paleolithic diet movement. Their "evolutionary discordance hypothesis" proposed that the diet of ancestral hunter-gatherers was healthier than that of contemporary people, and that the evolution from Paleolithic nutrition to a contemporary diet created a discordance that was connected to modern chronic diseases such as diabetes and heart disease. Paleolithic nutrition consisted of higher levels of protein and fat than the modern diet and lower levels of refined carbohydrates and **sodium**. In addition, Paleolithic humans were more active than their modern descendents.

Since 1985, different versions of the Paleo diet have hit the market. Though they are all based on Paleolithic eating patterns, there is generally some variation. For example, some proponents recommend eating a variety of very lean meats from animals raised as much as possible like those in the wild, while others encourage eating a large quantity of red meats with high fat content.

Though many people use Paleolithic diets to lose weight, they are intended as lifelong eating plans to promote good health. Portion control or counting calories and fat grams are not part of these plans. People are allowed to eat permitted foods until they feel full. The food choices allowed in these high-protein, **low-carbohydrate diets** are based on prehistoric nutrition.

The Paleo diet permits fruits, vegetables, meats, fish, eggs, nuts, and certain oils. Cereal grains, legumes (including peanuts and soy), dairy, and processed foods should be eliminated or severely reduced. When beginning the Paleo diet, it is advisable to slowly begin the transition to Paleo, gradually including more meals from the eating plan. Guidelines are relaxed during this transition period, which is intended to help the dieter stick to the diet in the long run.

Diet basics

Paleo diets are intended to include only foods that were available to humans more than 10,000 years ago. Prehistoric people ate many raw or nearly raw foods, but food on modern diets does not have to be eaten plain and raw—although a few Paleo diets do encourage that food be eaten very close to its raw state. Because of contemporary farming and food processing techniques, meats, poultry, seafood, and eggs should be cooked or dried to prevent the risk of foodborne illness.

Although wild grains existed during the Paleolithic period, many were very different than the grains grown today. They were unlikely to have been as robust and would have provided little nutrition, so grains—including rice, wheat, and corn—are forbidden on most Paleo diets.

Starchy vegetables such as potatoes are also forbidden, as are legumes. Many diets make exceptions for yams and sweet potatoes, especially for athletes, as they are a good source of carbohydrates.

No dairy products are allowed while on this diet. Milking did not occur until animals were domesticated, sometime after the Paleolithic age, so milk, cheese, butter, or any other food that comes from milking animals is not permitted. Alternatives for cow's milk include almond and coconut milks. Eggs are allowed, because eggs could have been found in bird's nests during foraging and hunting.

The other basic premise of Paleo diets is that nothing that requires technology can be eaten. Technology encompasses activities as diverse as agricultural methods to complex processing and canning. This rule excludes all forms of refined sugars and other processed foods. The Paleo Diet website (http://thepaleodiet.com) advises consumers to avoid food "if it contains salt or comes in a package, can, or box."

HUNTER-GATHERER MEATS. Although some foods that Paleolithic people ate are still available in the twenty-first century, modern diets focus on meats that are more common, such as beef and chicken. Some versions of the Paleo diet suggest eating meats higher in fat to promote a feeling of fullness, but others recommend selecting lean meats. Loren Cordain, author of *The Paleo Diet: Lose Weight and Get Healthy by Eating the Food You Were Designed to Eat*, believes that Paleolithic humans ate meat that was leaner because animals raised in the wild tended to have less fat and leaner muscle. Regardless of the type of meat selected, an emphasis is placed on choosing free-range and grass-fed products, which are considered by some to be healthier than meat from animals fed corn and grains.

EXERCISE. Different versions of the Paleo diet vary in their recommendations about the role of **exercise**. Some versions do not make recommendations, and others encourage significant amounts of exercise, especially outdoor exercise. This is because Paleolithic humans spent most of their time hunting and gathering food, which would have required significantly more physical activity than average humans engage in today.

Function

Paleo diets are intended to improve overall health and promote weight loss if needed. Advocates of the diets believe that the human body is not designed to process foods that were not consumed during the Paleolithic age, and that avoiding post-Paleolithic foods will lead to a decreased risk of many of the diseases prevalent in the industrialized world, such as **obesity**, diabetes, and heart disease.

Benefits

There are many benefits to losing weight if it is done at a moderate pace through healthy eating and exercise. Obesity is associated with increased risk of developing many adverse health conditions, including type 2 diabetes and cardiovascular disease, but these risks can be reduced if a healthy weight is reached. Regular exercise helps weight loss occur more quickly by helping burn excess calories and creating muscle mass and may also contribute to a reduced risk of disease.

In addition to weight loss, Paleo diets may provide other health benefits. Fresh fruits and vegetables are high in many **vitamins** and **minerals**, which are important for overall good health. Free-range, grass-fed lean meats may contain higher levels of **omega-3 fatty acids**, which are believed to have positive effects on the heart and cardiovascular system.

Advocates of Paleo diets maintain that people who follow these plans experience an immediate increase in energy, because their blood sugar and insulin concentration stabilizes on the low–glycemic load carbohydrates found in fruits and vegetables. Foods and drinks that contain carbohydrates are ranked on a glycemic index based on how they affect blood sugar levels. Low rankings start at 0, with the highest foods ranked at 100. Foods and beverages considered low rank at 55 or less. Examples of low-ranking foods include spinach, asparagus, broccoli, tomatoes, grapefruit, and apples.

Cordain claims that following a Paleo diet helps resolve conditions such as diabetes, high blood pressure, high **cholesterol**, **acne**, and **irritable bowel syndrome**. Further research is needed to substantiate these assertions, but some studies have shown promise that Paleo diets may help regulate blood glucose levels in people with type 2 diabetes.

Precautions

Anyone thinking about beginning a new diet should first consult a medical practitioner. Requirements for calories, fat, and nutrients could differ significantly from person to person, depending on gender, age, weight, and the presence of any diseases or conditions. Pregnant or **breastfeeding** women should be especially cautious, because deficiencies of vitamins or minerals could have a significant negative impact on a developing baby.

Dairy products and grains are part of traditionally accepted nutritional eating plans. The two food groups are recommended in the *2010 Dietary Guidelines for Americans* issued by the U.S. Department of Agriculture (USDA) and the Department of Health and Human Services (HHS). Grains and dairy products are also recommended by organizations such as the Academy of Nutrition and Dietetics (formerly the American Dietetic Association). Health experts recommend that people consume low-fat dairy products because they are rich in **calcium**, the primary mineral used for the body to build and maintain strong bones

WWW.BOOKBAZ.IR

and teeth. In addition, grains are a source of the dietary fiber that provides the bulk needed for a healthy digestive system.

A diet consisting primarily of meat will be more expensive than diets based on a more traditional food plan. In addition, critics of the various versions of the Paleo diet regard it as a fad diet, one that is nutritionally lacking and could be difficult to maintain on a long-term basis. Furthermore, they point out that although Paleolithic people did not have chronic conditions like diabetes and heart disease, the life expectancy of Stone Age people was 30 years old. Not only is that much shorter than the life expectancy today, but conditions such as type 2 diabetes and heart disease are more likely to develop later in life.

Risks

There are some risks with any diet. It can be difficult to get enough of some vitamins and minerals when eating a limited variety of foods. All versions of the Paleo diet exclude all milk and other dairy products. Because these foods are excellent sources of calcium, people following a Paleo diet will need to ensure that they are getting enough calcium in their diet. A lack of calcium can lead to many different diseases and conditions such as **osteoporosis** and **rickets**. Anyone beginning this diet should consult with their physician about whether or not it is safe and if they will need to take any vitamins or supplements.

Restricting carbohydrates could cause lethargy and **fatigue** due to low energy, at least initially. Limited carbohydrate intake also increases the risk of ketosis, a potentially serious medical condition. Carbohydrates provide the body's primary energy source in the form of glucose, which is produced during carbohydrate metabolism. Where carbohydrate intake is low, the body turns to fat for energy, producing ketones. Too many ketones in the body can lead to ketosis, a condition characterized by nausea, **headache**, fatigue, and **bad breath** and that can result in liver or kidney damage if sustained.

Eating unlimited amounts of foods could pose a health risk. Eating food high in calories without exercising could result in weight gain and put a person at risk medically. Versions of the Paleo diet that allow and encourage the consumption of large quantities of high-fat red meat could pose this danger. High-fat diets, especially diets high in animal fats, have been shown to increase the risk of cardiovascular disease. Versions of the diet that encourage the consumption of lean meats may not have this increased risk.

Diets that recommend large amounts of red meat and eggs and encourage the consumption of fattier meats are extremely controversial. Although high-fat, low-carb diets, such as the Atkins diet, have gained many followers, physicians, registered dietitians, and other health and science professionals continue to debate their various health benefits and risks. It is generally accepted that regularly eating a diet high in saturated fats, which are often found in high quantities in red meat, has a detrimental effect on health and can lead to increased incidence of cardiovascular disease. High intake of red meat is also associated with increased risk of colorectal cancer, thought to be due to N-nitrosos compounds produced when iron in meat breaks down. N-nitrosos are thought to be carcinogenic.

While fatty fish is a source of omega-3 fatty acids, the Academy of Nutrition and Dietetics and other organizations caution that it is also high in calories. Some types of seafood, such as tuna, may also contain mercury or other toxins.

Research and general acceptance

In a 2010 article titled "Paleolithic Nutrition: Twenty-Five Years Later," authors Konner and Eaton reviewed the research conducted during the 25 years following the publication of their first article about Paleolithic nutrition in 1985. The authors stated that initial results from studies were consistent with their original predictions.

The research they cited included a noncontrolled challenge study of nine sedentary but healthy volunteers who were not obese. Volunteers ate their usual diets for three days followed by three days of "ramp-up" diets. The volunteers then ate meat, fruit, vegetables, and nuts for ten days and did not consume grains, dairy products, and legumes. The authors stated that the group experienced "modest but significant" drops in blood pressure.

Another study involved 29 patients with ischemic heart disease (coronary heart disease) and either glucose intolerance or type 2 diabetes. During the 12-week study, 14 people followed a Paleolithic-based diet consisting of lean meat, fish, fruit, vegetables, root vegetables, eggs, and nuts. The remaining 15 people followed a Mediterranean-style diet that included whole grains, low-fat dairy products, vegetables, fruits, fish, oils, and margarines. After 12 weeks, the AUC (area under the curve) glucose level decreased by 26% in the Paleolithic group and 7% in the Mediterranean group. Waist circumference dropped 2.20 in. (5.6 cm) in the Paleolithic group and 1.14 in. (2.9 cm) in the Mediterranean group.

KEY TERMS

Blood glucose—The main sugar that the body makes from the food in the diet.

Carcinogen—A cancer-causing substance.

Diabetes mellitus—A condition in which the body either does not make or cannot respond to the hormone insulin. As a result, the body cannot use glucose (sugar). There are two types, type 1 or juvenile onset, and type 2 or adult onset.

Dietary supplement—A product, such as a vitamin, mineral, herb, amino acid, or enzyme, that is intended to be consumed in addition to an individual's diet with the expectation that it will improve health.

Glycemic index (GI)—A measurement of the speed at which the body converts carbohydrates in foods to blood glucose. The more rapidly a food's carbohydrates are converted to glucose, the higher its GI.

Ketones—Chemicals produced during the breakdown of fat.

Ketosis—An abnormal increase in the number of ketones in the body, produced when the liver breaks down fat into fatty acids and ketone bodies. Ketosis is a common side effect of low-carbohydrate diets or VLCDs. If continued for a long period of time, ketosis can cause serious damage to the kidneys and liver.

Mineral—An inorganic substance found in the earth that is necessary in small quantities for the body to maintain health. Examples include zinc, copper, iron.

Vitamin—A nutrient that the body needs in small amounts to remain healthy but that the body cannot manufacture for itself and must acquire through diet.

Both of these studies were extremely small and do not provide enough support for the diet's purported benefits. Some more recent research published in 2014 suggested that the Paleo diet was beneficial for weight loss and metabolic balance for 70 obese, postmenopausal women. However, like many diet studies, the research did not follow the women up for a year or more after completion of the study to see if they were able to maintain weight loss or health benefits of the diet.

According to the American Academy of Nutrition and Dietetics, sticking with the Paleo diet for a length of time is one of the drawbacks of the plan. A review of the diet by a member of the academy says that the Paleo diet is beneficial in encouraging more fruits and vegetables in the diet and less added sugar and salt, which aligns with the 2010 Dietary Guidelines for Americans. However, the higher emphasis on fat and protein and lower emphasis on whole grains, dairy, and legumes, throws off the dietary balance that has been proven in many scientific studies to provide the vitamins and minerals modern people need in their daily diets.

Palliative cancer therapy *see* **Cancer therapy, palliative**

Palliative care

Definition

Palliative care is a multidisciplinary approach to relieving physical, psychological, emotional, social, and spiritual suffering in patients with chronic or terminal illnesses. Palliative care for children includes providing comfort and support for the entire family, regardless of whether the child is in home or hospice care.

Purpose

The purpose of palliative care is to improve the quality of life for patients and their families. The primary goal is to relieve **pain** and other physical symptoms—such as nausea or fatigue—caused by diseases, conditions, and treatments. Palliative care also attempts to minimize side effects from medical interventions. In addition, palliative care aims to relieve psychological symptoms, such as **anxiety** or depression, and to provide comfort and support for patients and their families. Pediatric palliative care helps children lead lives that are as normal and happy as possible under the circumstances.

Demographics

It has been estimated that, worldwide, seven million children and their families could benefit from palliative care. In the United States, approximately 27,000 children die annually from illness or other medical conditions. Although the number of pediatric palliative care programs is growing, the number of parents who are solely responsible for overseeing their children's **pain management** and recovery is also increasing, as most children are sent home from the hospital within hours of surgery. Approximately 84% of pediatric surgeries in the United States are performed on an outpatient basis.

Although some children receive treatment and services from adult palliative care programs, of the approximately 2,500 home-, freestanding-, and hospital-based hospice programs in the United States, only about 10% are pediatric. It has been estimated that hospice care is available to less than 1% of American children in need of it.

Description

Children living with serious chronic illnesses—including certain cancers, HIV/AIDS, **cystic fibrosis**, **heart disease**, lung disease, or kidney failure—can suffer from significant physical symptoms, pain, and

emotional distress. Children undergoing medical treatments can also have physical, psychological, and emotional symptoms that require palliative care. In addition to pain, symptoms such as nausea, weakness, bowel and bladder problems, **constipation**, breathing difficulties, **fatigue**, and mental confusion are treated through palliative care. Although palliative care usually intensifies toward the end of a terminal illness, children may receive palliative care at any stage of—and throughout—any illness.

Palliative care for cancer may include **chemotherapy**, **radiation therapy**, or surgery. Although these treatments may not cure cancer that has metastasized or spread, they can diminish the cancer, improve or eliminate symptoms, at least for a period of time, and extend life.

Pediatric illness can have a devastating impact on families. Because many serious childhood illnesses are quite rare, parents and children are often forced to travel to specialized treatment centers. Jobs and support systems can be lost and financial resources depleted. Parents may be at risk for **alcoholism** or drug abuse. The sick child's siblings may experience lack of attention. Therefore, pediatric palliative care uses a holistic approach to address the physical, cultural, psychological, emotional, spiritual, and practical needs of the entire family.

Pediatric palliative care differs from adult palliative care for a variety of reasons:

- Serious illnesses in children are relatively rare in developed countries and the course of disease in children is often unpredictable.
- There are often large uncertainties in the prognoses and survival times for life-threatening illnesses in children.
- Children are very resilient and sometimes recover after being close to death.
- Even children with conditions that ultimately prove fatal often have periods of relative health during which they lead comparatively normal lives.
- Pediatricians are strongly committed to their patients and usually want to remain in charge of their care plans.
- Most parents both want and need to be involved in—and have at least some control over—their child's care. Pediatric palliative care encourages their participation.
- Parents are usually not willing to choose between treatments aimed at disease management or a cure and those aimed at making the child comfortable.
- Childhood diseases are usually treated very aggressively with the goal of extending life at any cost. For these reasons, parents often choose "heroic" medical treatments that have only a small chance of success

There are other significant differences between pediatric and adult palliative care:

- Children have unique developmental and psychosocial needs.
- Children are strongly connected to their families and their schools.
- Children may lack verbal skills for expressing their feelings and needs.
- Identifying sources of pain and the drugs and therapies that can effectively manage the pain can be difficult with young children.
- Children are usually dependent on their parents for medical decision-making. However, children as young as seven to 10 can often articulate informed opinions about their medical care. Adolescents expect to participate in medical decision-making. Members of a palliative care team may help children and teens to understand their condition and to participate in discussions of treatment options.
- Siblings and grandparents may complicate medical decision-making and other family issues.
- Pediatric palliative care focuses on the entire family rather than on the patient alone.
- Because the initial diagnosis is often the most emotionally difficult time for families, pediatric palliative care usually begins at the time of diagnosis.
- Pediatric palliative care may be much more integrated with medical treatment than adult palliative care, and it can be an important component of any remission or cure.

Pediatric palliative care is being increasingly integrated into treatment protocols and therapies. A palliative care team may include:

- physicians
- specialists
- nurses

Pediatric palliative care is more likely to take place in the home than in a hospital or hospice for a variety of reasons:

- Although hospice care always includes palliative care, it is generally defined as end-of-life care for

WWW.BOOKBAZ.IR

patients with a six-month prognosis who will receive no further lifesaving treatments. This definition is often not applicable to children.

- Most hospices do not have pediatric-specific services.
- There is little or no financial reimbursement for pediatric hospice or home care.
- Many families prefer to have their child die at home and many pediatric palliative care programs include end-of-life planning.
- Studies have found that the overall quality of care is generally better in the home than in a hospital or hospice.

Origins

Pediatric palliative care is a relatively new medical subspecialty. The first pediatric palliative **home care** program in the United States was established in Connecticut in 1974. Since the 1980s a variety of home- and hospice-based pediatric palliative care programs have been established across the United States and around the world. In 1984, Dr. Burton Grebin opened St. Mary's Hospital for Children as a comprehensive palliative care center in Bayside, New York. Grebin sought to normalize the children's environment: St. Mary's has its own New York City Public School; the children wear street clothes and play and socialize; families are encouraged to visit and spend the night. The St. Mary's program includes counseling for parents and siblings.

Benefits

Palliative care can:

- ensure that discomfort and pain are managed adequately
- help normalize life for seriously ill children and their families
- encourage parental participation and ease emotional stress and grief
- promote informed medical decision-making
- promote coordinated medical care and services
- lead to better medical outcomes
- reduce hospital and emergency-room visits, thereby making more efficient use of healthcare spending
- provide families with improved access to resources and services, such as therapy and respite care
- provide children with the most peaceful end of life as possible

Precautions

New medical technologies have complicated treatment decisions for parents. Newborns are often subjected to stressful and painful tests and procedures, even when their condition or illness is incompatible with life. Overwhelmed parents are often unaware of the long-term consequences of the medical decisions that they are asked to make, especially when they are dealing with multiple specialists. In addition, language and cultural barriers can exacerbate communication problems between parents, physicians, and palliative care providers.

It can be very difficult for young children to understand why they are undergoing painful procedures for diagnosis and treatment and many parents want to protect their child from a serious prognosis. However, studies have found that even very young children can understand the seriousness of their disease and that open communication between children and their parents and care providers can help alleviate their fears and maintain hope.

Infants and children are often unable to communicate symptoms and specific sources of discomfort and pain. A major component of pediatric palliative care is the identification and treatment of such symptoms. Prescribing pain medications for children is a specialized skill, because dosages are based on body weight and because children's bodies metabolize medications differently than adults. Furthermore, children often cannot swallow pills. Palliative caregivers must work closely with pharmacists to develop syrups, dissolvable capsules, or skin patches. It is helpful for children to take a medication before leaving the hospital to ensure that they can swallow it. Parents can also request that their pharmacists add their child's favorite flavor to medications.

Parents are often reluctant to administer pain medications, either because they fear that the child will become addicted to **narcotics** or because they are waiting for the child to cry or complain of severe pain. However, pain can interfere with a child's recovery by triggering the body's **stress** response. Prescriptions for painkillers should be filled immediately, so that the medication is available in the middle of the night. Parents must also learn to recognize signs that their child is in pain. These may include:

- fussiness
- refusing to eat or drink
- becoming quiet or withdrawn
- sleep disturbances
- mood or behavior changes

KEY TERMS

Children's hospice—A holistic philosophy that addresses the physical, emotional, social, and spiritual needs of children with life-threatening illnesses, as well as the needs of their families.

Chronic—An illness or condition of long duration, frequent recurrence, or slow progression.

Hospice—A facility or program that provides for the physical and emotional needs of the terminally ill in a caring environment.

Opiate—A drug containing or derived from opium—such as codeine, morphine, and heroin—that alleviates pain and induces sleep.

Palliative treatment—Treatments—such as chemotherapy, radiation therapy, or surgery—that ease the symptoms of a disease without curing it.

Respite care—Temporary care of a patient to provide parents or other caregivers with a period of physical, mental, and emotional rest.

Although medical associations, including the American Academy of Pediatrics, have endorsed pediatric palliative care, it is not universally supported. Some physicians do not believe it is medically necessary and many hospitals claim they cannot afford it. Palliative care is poorly reimbursed by Medicaid and it has been more difficult to demonstrate cost savings from reduced emergency care and hospital stays with pediatric palliative care than with adult programs.

Preparation

Palliative care for children usually begins with the diagnosis of a chronic or life-threatening illness. Preparation may include:

- educating family members about the child's disease or condition
- informing family members about treatment and care options
- advising on various aspects of home care, including administering medication and recognizing symptoms that require immediate attention
- arranging home support services, possibly including transportation, shopping, and meal preparation
- arranging respite care
- helping the family plan for financial strains caused by the child's illness
- helping the family develop a support network

Aftercare

Palliative aftercare may include:

- helping families prepare for a child's death
- helping with funeral and other arrangements
- grief and bereavement counseling and support groups

Risks

Physicians who are inexperienced in treating pain in terminally ill children may be reluctant to prescribe opiates, including morphine. Even when prescribed, parents may withhold medication because of fear of side effects or **addiction**. Parents may consider hastening a suffering child's death because they are unaware of the legal options for pain relief, including sedating a child into unconsciousness.

Margaret Alic, PhD

Palpitations

Definition

The term palpitation refers to a sensation in which a person is aware of an irregular, hard, or rapid heartbeat.

Description

Palpitations mean that the heart is not behaving normally. It can appear to skip beats, beat rapidly, beat irregularly, or thump in the chest. Although palpitations are very common and often harmless, they can be frightening to a person, who is usually unaware of his or her heartbeat.

Palpitations can also be a sign of serious heart trouble. Palpitations that are caused by certain types of abnormal heart rhythms (**arrhythmias**) can be serious, and even fatal if left untreated. Recognizable arrhythmias are present in a small number of patients who have palpitations. Immediate medical attention should be sought for palpitations that feel like a very fast series of heartbeats, last more than two or three minutes, and are unrelated to strenuous physical activity, obvious fright, or anger. Medical attention should also be sought if palpitations are accompanied by chest **pain**, **dizziness**, **shortness of breath**, or an overall feeling of weakness.

Most people have experienced a skipped or missed heartbeat, which is really an early beat and not a skipped beat at all. After a premature heartbeat, the heart rests for an instant then beats with extra force, making a person feel as if the heart has skipped a beat. This type of palpitation is nothing to worry about unless it occurs frequently. Severe palpitations feel like a thudding or fluttering sensation in the chest. After chest pain, palpitations are the most common reason that people are referred for cardiology evaluation.

Causes and symptoms

Palpitations can be caused by **anxiety**, arrhythmias, **caffeine**, certain medications, cocaine and amphetamines, emotional **stress**, overeating, panic, somatization, and vigorous **exercise**. There may be no other symptoms. But, anxiety, dizziness, shortness of breath, and chest pain may be signs of more severe arrhythmias.

Diagnosis

Palpitations are diagnosed through a medical history, a **physical examination**, an electrocardiogram

(ECG), and screening for psychiatric disorders. It is often difficult to distinguish palpitations from **panic disorder**, a common problem in which a person experiences frequent and unexplained "fight-or-flight" responses, which is the body's natural physical reaction to extreme danger or physical exertion, but without the obvious external stimulus.

To accurately diagnose palpitations, one of the irregular heartbeats must be "captured" on an EKG, which shows the heart's activity. Electrodes covered with a type of gel that conducts electrical impulses are placed on the patient's chest, arms, and legs. These electrodes send impulses of the heart's activity to a recorder, which traces them on paper. This **electrocardiography** test takes about 10 minutes and is performed in a physician's office or hospital. Because palpitations are unlikely to occur during a standard EKG, **Holter monitoring** is often performed. In this procedure, the patient wears a small, portable tape recorder that is attached to a belt or shoulder strap and connected to electrode disks on his or her chest. The Holter monitor records the heart's rhythm during normal activities. Some medical centers are now using event recorders that the patient can carry for weeks or months. When palpitations occur, the patient presses a button on the device, which captures the information about the palpitations for physician evaluation. Later the recording can be transmitted over the telephone line for analysis.

Treatment

Most palpitations require no treatment. Persistent palpitations can be treated with small doses of a beta blocker. **Beta blockers** are drugs that tend to lower blood pressure. They slow the heart rate and decrease the force with which the heart pumps. If the cause of the palpitations is determined to be an arrhythmia, medical or surgical treatment may be indicated, although surgery is rarely needed.

Alternatives

Alternative treatments for palpitations should be used only as a complement to traditional medicine. Alternative treatments include: **aromatherapy**, Chinese herbs, herbal therapies, **homeopathic medicine**, exercise, mind/body medicine, and diet and **nutrition**. In aromatherapy, adding citrus oils to bath water may help with minor palpitations. Some Chinese herbs can also help, but others can worsen arrhythmias, so a qualified herbalist should be consulted. Herbal therapies such as hawthorn (*Crataegus laevigata*) and motherwort (*Leonurus cardiaca*) can help with palpitations.

KEY TERMS

Arrhythmia—Any variation from the normal heartbeat. Some arrhythmias are harmless, while others, such as ventricular tachycardia, ventricular fibrillation, and ventricular standstill, can be fatal.

Somatization—Anxiety converted into physical symptoms. Somatization is a sign of panic disorder.

Homeopathic remedies such as *Lachesis, Digitalis,* and *Aconite* (*Aconitum nnapellus*) may be used to control palpitations but should be taken only when prescribed by a homeopathic physician. Mind/body medicine such as **meditation** and **yoga** can help the person relax, eliminating or reducing palpitations caused by anxiety or stress. Reducing or eliminating tea, cola, coffee, and chocolate, and consuming adequate amounts of the **mineralscalcium**, magnesium, and potassium can help reduce or eliminate palpitations. Alternative treatments should be used with care, as the benefits of many such treatments have not been confirmed by scientific research.

Prognosis

Most palpitations are harmless, but some can be a sign of heart trouble, which could be fatal if left untreated.

Prevention

Palpitations not caused by arrhythmias can be prevented by reducing or eliminating anxiety and emotional stress, and reducing or eliminating consumption of tea, cola, coffee, and chocolate. Exercise can also help, but a treadmill **stress test** performed by a physician should be considered first to make sure that exercise is safe.

Pancreas transplantation

Definition

Pancreas transplantation is a surgical procedure in which a diseased pancreas is replaced with a healthy pancreas that has been obtained from an immunologically compatible cadavear or living donor.

Purpose

The pancreas is an organ that secretes insulin, a peptide hormone that regulates glucose (blood sugar) metabolism. Patients with type 1 diabetes have experienced partial or complete damage to the insulin-producing beta cells of the pancreas. Consequently, they are unable to generate sufficient insulin to control blood glucose levels. Long-term uncontrolled high blood glucose levels can cause damage to every system of the body, so type 1 patients must inject insulin to do the work of the beta cells. Pancreas transplantation allows the body to once again make and secrete its own insulin, and establishes insulin independence for these individuals.

National transplant waiting list by organ type (September 2014)

Organ needed	Persons waiting
Kidney	101,116
Liver	15,679
Heart	4,016
Kidney/Pancreas	4,016
Lung	1,614
Pancreas	1,182
Intestine	259
Heart/Lung	53

(Table by PreMediaGlobal. © Cengage Learning®.)

Demographics

It is estimated that about 1.4 million people in the United States have type 1 **diabetes mellitus** (also called insulin-dependant diabetes or juvenile diabetes). Among these individuals, the best candidates for pancreas transplantation are typically:

- between the ages of 20 and 40
- those who have extreme difficulty regulating their glucose levels with insulin therapy (a condition called brittle diabetes)
- those who have few secondary complications of diabetes
- those who are in good cardiovascular health

Pancreas-only transplants account for about 10% of the 1200 pancreas transplants performed each year in the United States. More common is the combined kidney-pancreas transplant, or simultaneous pancreas-kidney transplantation (SPK), which is performed in about 75% of patients. The remaining 15% of patients receive a PAK, or pancreas after kidney transplant, according to the United Network for Organ Sharing (UNOS). There are about 100 medical centers in the United States that perform pancreas transplantations.

Description

Once a donor pancreas is located and **tissue typing** deems it compatible, the patient is contacted and prepared for surgery. Blood tests, a **chest x ray**, and an

KEY TERMS

Cadaver organ—A pancreas, kidney, or other organ from a brain-dead organ donor.

Duodenum—The section of the small intestine immediately after the stomach.

electrocardiogram (ECG) are performed and an intravenous (IV) line is started for fluid and medication administration. Once the transplant procedure is ready to start, general **anesthesia** is administered.

The surgeon makes an incision under the ribs and locates the pancreas and duodenum. The pancreas and duodenum (part of the small intestine) are removed. The new pancreas and duodenum are then connected to the patient's duodenum, and the blood vessels are sutured together to restore blood flow to the new pancreas. The patient's original pancreas is left in place.

Replacing the duodenum allows the pancreas to drain into the gastrointestinal system. The transplant can also be done creating bladder drainage. Bladder drainage makes it easier to monitor organ rejection because pancreatic secretions can be measured in the patient's urine. Once the new pancreas is in place, the abdomen and skin are sutured closed. This surgery is often done at the same time as kidney **transplant surgery**.

Diagnosis/Preparation

After the patient and doctor have decided on a pancreas transplant, a complete immunological study is performed to match the patient to a donor. An extensive medical history and **physical examination** is performed, including radiological exams, blood and urine tests, and psychological evaluation. Once the patient is approved for transplant, he or she will be placed on the United Network for Organ Sharing (UNOS) Organ Center waiting list. The timing of surgery depends on the availability of a donated living or cadaver organ.

Aftercare

Patients receiving a pancreas transplantation are monitored closely for organ rejection. The average hospital stay is three weeks, and it takes about six months to recover from surgery. Patients will take **immunosuppressant drugs** for the rest of their lives.

Results

In a successful transplant, the pancreas begins producing insulin, bringing the regulation of glucose back under control. Natural availability of insulin prevents the development of additional complications associated with diabetes, including kidney damage, vision loss, and nerve damage. Many patients report an improved quality of life.

Morbidity and mortality rates

According to the Mayo Clinic, the transplanted pancreas is still functioning after one year in about 87% of people who receive a simultaneous pancreas-kidney transplant. After five years, the rate drops to 72%. In about 77% of people who receive a pancreas-after-kidney transplant, the transplanted pancreas is still functioning after one year; five years after transplant, the rate drops to 59%. In about 85% of people who receive a pancreas-only transplant, the transplanted pancreas is still functioning after one year. That rate is about 52% after five years.

Risks

Diabetes and poor kidney function greatly increase the risk of complications from anesthesia during surgery. Organ rejection, excessive bleeding, and infection are other major risks associated with this surgery.

The reason that simultaneous kidney-pancreas transplants and pancreas-after-kidney transplants are performed more frequently than pancreas-only transplants is the relative risk of immunosuppressant drugs in people with diabetes. People with type 1 diabetes are already at risk for autoimmune problems, are more prone to infections, and have a complicated medical history that makes suppressing the immune system unadvisable.

On the other hand, diabetes is also the number one cause of **chronic kidney failure**, or end-stage renal disease (ESRD), which makes this group more likely to eventually require a kidney transplant for survival. In those patients with diabetes who will receive or are already receiving immunosuppressive treatment for a life-saving kidney transplant, a pancreas transplant can return their ability to self-produce insulin.

Patients with type 1 diabetes considering pancreas transplantation alone must weigh the risks and benefits of the procedure and decide with their doctors whether life-long treatment with immunosuppressive drugs is preferable to life-long insulin dependence.

WWW.BOOKBAZ.IR

Alternatives

Innovations in islet cell transplants, a procedure that involves transplanting a culture of the insulin-producing islet cells of a healthy pancreas to a patient with type 1 diabetes, have increased the frequency of this procedure. The Edmonton Protocol, a type of islet cell transplant developed in 1999 by Dr. James Shapiro at the University of Alberta (Canada), uses a unique immunosuppresant drug regimen that has dramatically improved success rates of the islet transplant procedure. As of early 2014, the Edmonton Protocol is still considered investigational in the United States, and a number of clinical trials are ongoing. One center that is recruiting patients for clinical trials of islet transplantation is the Schulze Diabetes Institute of the University of Minnesota.

Researchers in Japan and elsewhere are also investigating stem cells as a source of insulin-producing cells available for transplantation. This research is promising as of 2014.

REVISED BY REBECCA J. FREY, PhD

Pancreatectomy

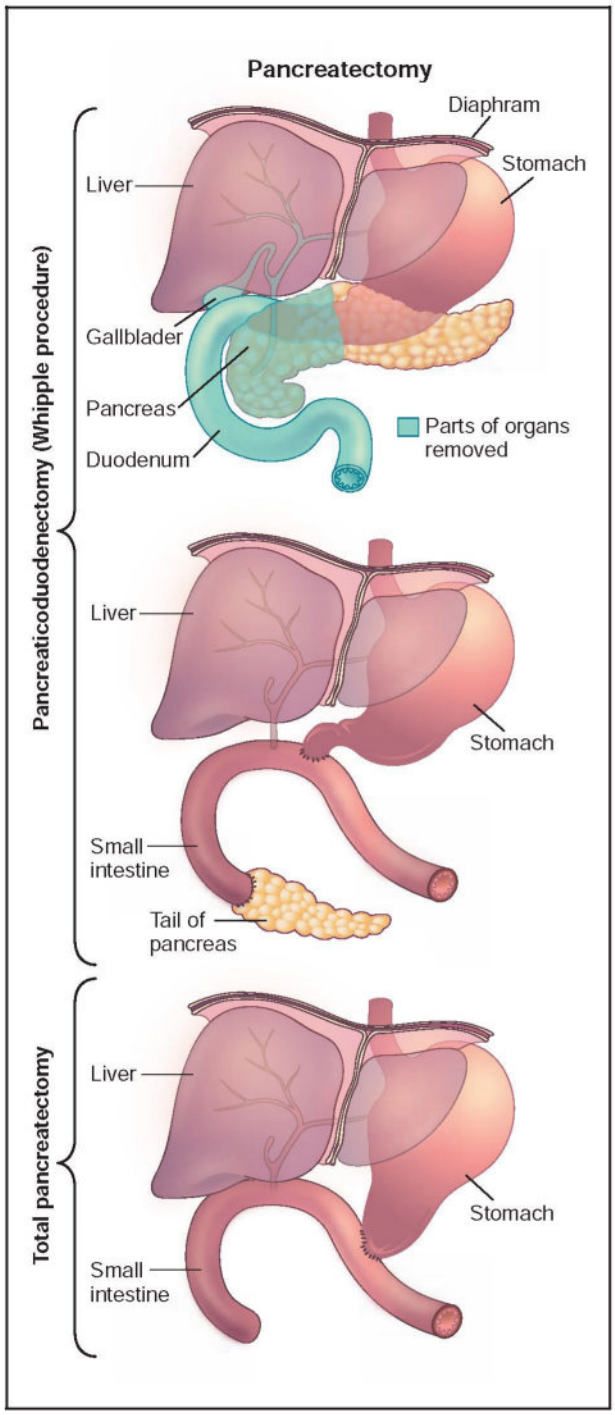
Definition

A pancreatectomy is the surgical removal of the pancreas. A pancreatectomy may be total, in which case the entire organ is removed, usually along with the spleen, gallbladder, common bile duct, and portions of the small intestine and stomach. A pancreatectomy may also be distal, meaning that only the body and tail of the pancreas are removed, leaving the head of the organ attached. When the duodenum is removed along with all or part of the pancreas, the procedure is called a pancreaticoduodenectomy, which surgeons sometimes refer to as Whipple's procedure. Pancreaticoduodenectomies are increasingly used to treat a variety of malignant and benign diseases of the pancreas. This procedure often involves removal of the regional lymph nodes as well.

Purpose

A pancreatectomy is the most effective treatment for cancer of the pancreas, an abdominal organ that secretes digestive enzymes, insulin, and other hormones. The thickest part of the pancreas near the duodenum (a part of the small intestine) is called the head, the middle part is called the body, and the thinnest part adjacent to the spleen is called the tail.

While surgical removal of tumors in the pancreas is the preferred treatment, it is only possible in the 10–15% of patients who are diagnosed early enough for a potential cure. Patients who are considered suitable for surgery usually have small tumors in the head of the pancreas (close to the duodenum, or first part of the small intestine), have **jaundice** as their initial symptom, and have no evidence of metastatic disease



Two types of pancreatectomies: pancreaticoduodenectomy (top, also known as the Whipple procedure) and total pancreatectomy (bottom). *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

(spread of cancer to other sites). The stage of the cancer will determine whether the pancreatectomy to be performed should be total or distal.

A partial pancreatectomy may be indicated when the pancreas has been severely injured by **trauma**, especially injury to the body and tail of the pancreas. While such surgery removes normal pancreatic tissue as well, the long-term consequences of this surgery are minimal, with virtually no effects on the production of insulin, digestive enzymes, and other hormones.

Chronic **pancreatitis** is another condition for which a pancreatectomy is occasionally performed. Chronic pancreatitis—or continuing inflammation of the pancreas that results in permanent damage to this organ—can develop from long-standing, recurring episodes of acute (periodic) pancreatitis. This painful condition usually results from alcohol abuse or the presence of **gallstones**. In most patients with the alcohol-induced disease, the pancreas is widely involved, therefore, surgical correction is almost impossible.

Description

A pancreatectomy can be performed through an open surgery technique, in which case one large incision is made, or it can be performed laparoscopically, in which case the surgeon makes four small incisions to insert tube-like surgical instruments. The abdomen is filled with gas, usually carbon dioxide, to help the surgeon view the abdominal cavity. A camera is inserted through one of the tubes and displays images on a monitor in the operating room. Other instruments are placed through the additional tubes. The laparoscopic approach allows the surgeon to work inside the patient's abdomen without making a large incision.

If the pancreatectomy is partial, the surgeon clamps and cuts the blood vessels, and the pancreas is stapled and divided for removal. If the disease affects the splenic artery or vein, the spleen is also removed.

If the pancreatectomy is total, the surgeon removes the entire pancreas and attached organs. He or she starts by dividing and detaching the end of the stomach. This part of the stomach leads to the small intestine, where the pancreas and bile duct both attach. In the next step, he removes the pancreas along with the connected section of the small intestine. The common bile duct and the gallbladder are also removed. To reconnect the intestinal tract, the stomach and the bile duct are then connected to the small intestine.

During a pancreatectomy procedure, several tubes are also inserted for postoperative care. To prevent tissue fluid from accumulating in the operated site, a temporary drain leading out of the body is inserted, as

KEY TERMS

Chemotherapy—A cancer treatment that uses synthetic drugs to destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Computed tomography (CT) scan—An imaging technique that creates a series of pictures of areas inside the body, taken from different angles. The pictures are created by a computer linked to an x-ray machine.

Endoscopic retrograde cholangiopancreatography (ERCP)—A procedure to x ray the ducts (tubes) that carry bile from the liver to the gallbladder and from the gallbladder to the small intestine.

Laparoscopy—In this procedure, a laparoscope (a thin, lighted tube) is inserted through an incision in the abdominal wall to determine if the cancer is within the pancreas only or has spread to nearby tissues and if it can be removed by surgery later. Tissue samples may be removed for biopsy.

Magnetic resonance imaging (MRI)—A procedure in which a magnet linked to a computer is used to create detailed pictures of areas inside the body.

Pancreas—A large gland located on the back wall of the abdomen, extending from the duodenum (first part of the small intestine) to the spleen. The pancreas produces enzymes essential for digestion, and the hormones insulin and glucagon, which play a role in diabetes.

Pancreaticoduodenectomy—Removal of all or part of the pancreas along with the duodenum. Also known as "Whipple's procedure" or "Whipple's operation."

Pancreatitis—Inflammation of the pancreas, either acute (sudden and episodic) or chronic, usually caused by excessive alcohol intake or gallbladder disease.

Positron emission tomography (PET) scan—An imaging system that creates a picture showing the location of tumor cells in the body. A substance called radionuclide dye is injected into a vein, and the PET scanner rotates around the body to create the picture. Malignant tumor cells show up brighter in the picture because they are more active and take up more dye than normal cells.

Radiation therapy—A treatment using high energy radiation from x-ray machines, cobalt, radium, or other sources.

Ultrasonogram—A procedure where high-frequency sound waves that cannot be heard by human ears are bounced off internal organs and tissues. These sound waves produce a pattern of echoes which are then used by the computer to create sonograms, or pictures of areas inside the body.

well as a **gastrostomy** or g-tube leading out of the stomach in order to help prevent **nausea and vomiting**. A jejunostomy or j-tube may also be inserted into the small intestine as a pathway for supplementary feeding.

Diagnosis/Preparation

Patients with symptoms of a pancreatic disorder undergo a number of tests before surgery is even considered. These can include ultrasonography, x-ray examinations, **computed tomography scans** (CT scan), and **endoscopic retrograde cholangiopancreatography** (ERCP), a specialized imaging technique to visualize the ducts that carry bile from the liver to the gallbladder. Tests may also include **angiography**, another imaging technique used to visualize the arteries feeding the pancreas, and needle aspiration **cytology**, in which cells are drawn from areas suspected to contain cancer. Such tests are required to establish a correct diagnosis for the pancreatic disorder and in the planning the surgery.

Since many patients with pancreatic cancer are undernourished, appropriate nutritional support, sometimes by **tube feedings**, may be required prior to surgery.

Some patients with pancreatic cancer deemed suitable for a pancreatectomy will also undergo **chemotherapy** and/or **radiation therapy**. This treatment is aimed at shrinking the tumor, which will improve the chances for successful surgical removal. Sometimes, patients who are not initially considered surgical candidates may respond so well to chemoradiation that surgical treatment becomes possible. Radiation therapy may also be applied during the surgery (intraoperatively) to improve the patient's chances of survival, but this treatment is not yet in routine use. Some studies have shown that intraoperative radiation therapy extends survival by several months.

Patients undergoing **distal pancreatectomy** that involves removal of the spleen may receive preoperative medication to decrease the risk of infection.

Aftercare

Pancreatectomy is major surgery. Therefore, extended hospitalization is usually required with an average hospital stay of two to three weeks.

Some pancreatic cancer patients may also receive combined chemotherapy and radiation therapy after surgery. This additional treatment has been clearly shown to enhance survival rates.

After surgery, patients experience **pain** in the abdomen and are prescribed pain medication. Follow-up exams are required to monitor the patient's recovery and remove implanted tubes.

A total pancreatectomy leads to a condition called pancreatic insufficiency, because food can no longer be normally processed with the enzymes normally produced by the pancreas. Insulin secretion is likewise no longer possible. These conditions are treated with pancreatic enzyme replacement therapy, which supplies digestive enzymes; and with insulin injections. In some case, distal pancreatectomies may also lead to pancreatic insufficiency, depending on the patient's general health condition before surgery and on the extent of pancreatic tissue removal.

Results

After a total pancreatectomy, the body loses the ability to secrete insulin, enzymes, and other substances; therefore, the patient has to take supplements for the rest of his or her life.

Patients usually resume normal activities within a month after surgery, although they are asked to avoid heavy lifting for six to eight weeks and not to drive as long as they take narcotic medication.

When a pancreatectomy is performed for chronic pancreatitis, the majority of patients obtain some relief from pain. Some studies report that one-half to three-quarters of patients become free of pain.

Morbidity and mortality rates

The mortality rate for pancreatectomy has decreased in recent years to 5–10%, depending on the extent of the surgery and the experience of the surgeon. A study of 650 patients at Johns Hopkins Medical Institution, Baltimore, found that only nine patients, or 1.4%, died from complications related to surgery.

Unfortunately, pancreatic cancer is the most lethal form of gastrointestinal malignancy. However, for a highly selective group of patients, a pancreatectomy offers a chance for cure, especially when performed by experienced surgeons. The overall five-year survival rate for patients who undergo pancreatectomy for pancreatic cancer is about 10%; patients who undergo pancreaticoduodenectomy have a 4–5% survival at five years. The risk for tumor recurrence is thought to be unaffected by whether the patient undergoes a total pancreatectomy or a pancreaticoduodenectomy, but is increased when the tumor is larger than 1.2 in (3 cm) and the cancer has spread to the lymph nodes or surrounding tissue.

Risks

There is a fairly high risk of complications associated with any pancreatectomy procedure. A recent Johns Hopkins study documented complications in 41% of cases. The most devastating complication is postoperative bleeding, which increases the mortality risk to 20–50%. In cases of postoperative bleeding, the patient may be returned to surgery to find the source of hemorrhage, or may undergo other procedures to stop the bleeding.

One of the most common complications from a pancreaticoduodenectomy is delayed gastric emptying, a condition in which food and liquids are slow to leave the stomach. This complication occurred in 19% of patients in the Johns Hopkins study. To manage this problem, many surgeons insert feeding tubes at the original operation site, through which nutrients can be fed directly into the patient's intestines. This procedure, called enteral **nutrition**, maintains the patient's nutrition if the stomach is slow to recover normal function. Certain medications, called promotility agents, can help move the nutritional contents through the gastrointestinal tract.

The other most common complication is pancreatic anastomotic leak. This is a leak in the connection that the surgeon makes between the remainder of the pancreas and the other structures in the abdomen. Most surgeons handle the potential for this problem by checking the connection during surgery.

Pancreatic cancer, endocrine

Definition

Endocrine pancreatic cancer is a disease in which cancerous cells originate within the tissues of the pancreas that produce hormones.

Description

The pancreas is a 6–8 in (15–20 cm) long, slipper-shaped gland located in the abdomen. It lies behind the stomach, within a loop formed by the small intestine. Other nearby organs include the gallbladder, spleen, and liver. The pancreas has a wide end (head), a narrow end (tail), and a middle section (body). A healthy pancreas is important for normal food digestion and plays a critical role in the body's metabolic processes. The pancreas has two main functions, each performed by distinct types of tissue. The exocrine tissue secretes fluids into the other organs of the digestive system, while the endocrine tissue secretes substances that are circulated in the bloodstream. The exocrine pancreas makes up the vast majority of the gland; it produces pancreatic juices containing enzymes that help break down proteins and fatty food. The endocrine tissue of the pancreas makes up only 2% of the gland's total mass. It consists of small patches of cells that produce hormones (like insulin) that control how the body stores and uses nutrients. These patches are called islets (islands) of Langerhans or islet cells and are interspersed evenly throughout the pancreas. Each islet contains approximately 1,000 endocrine cells and a dense network of capillaries (tiny blood vessels), which allows immediate entry of hormones into the circulatory system.

Pancreatic tumors are classified as either exocrine or endocrine tumors depending on which type of tissue they arise from within the gland. Endocrine tumors of the pancreas are very rare, accounting for only 5% of all pancreatic cancers. The majority of endocrine pancreatic tumors are functional adenocarcinomas that overproduce a specific hormone. There are several types of islet cells and each produces its own hormone or peptide (small protein molecule). Functional endocrine tumors are named after the hormone they secrete. Insulinoma is the most common tumor of the endocrine pancreas. Patients with this disease usually develop **hypoglycemia** due to increased insulin production that leads to abnormally low blood sugar levels. **Gastrinoma**, a disease in which gastrin (hormone that stimulates stomach acid production) is overproduced, causes multiple **ulcers** in the upper gastrointestinal (GI) tract. Gastrinoma was first described in patients with a rare form of severe peptic ulcer disease known as Zollinger-Ellison syndrome (ZES). The less common glucagonoma causes mild diabetes due to excess glucagon (hormone that stimulates glucose production) secretion. Other rare islet cell tumors include vipoma (vasoactive intestinal peptide) and somatostatinoma. Nonfunctional pancreatic endocrine tumors are not associated with an excess production of any hormone and can be difficult to distinguish from **exocrine pancreatic cancer**. Cancers of the endocrine pancreas are relatively slow-growing compared to the more common ductal adenocarcinomas of the exocrine pancreas.

Between one and four cases of insulinoma occur per million people per year, and 90% of these tumors are benign. They occur mostly between the ages of 50 and 60 and affect men and women equally. Less than three cases of gastrinoma per million people are diagnosed each year, but it is the most common functional islet cell tumor in patients with multiple endocrine tumors, a condition known as multiple endocrine neoplasia (MEN) syndrome. Vipoma and glucagonoma are even rarer and they occur more frequently in women. Somatostatinoma is exceedingly uncommon, and less than 100 cases have been reported worldwide. Nonfunctional islet cell cancers account for approximately one-third of all cancers of the endocrine pancreas, and the majority of these are malignant.

Causes and symptoms

There are no known causes of islet cell cancer, but a small percentage of cases occur due to hereditary syndromes such as MEN. This is a condition that frequently causes more than one tumor in several endocrine glands, such as the parathyroid and pituitary, in addition to the islet cells of the pancreas. Twenty-five percent of gastrinomas and less than 10% of insulinomas occur in MEN patients. Von Hippel-Lindau (VHL) syndrome is another genetic disorder that causes multiple tumors, and 10–15% of VHL patients will develop islet cell cancer.

Symptoms vary among the different islet cell cancer types. Insulinoma causes repeated episodes of hypoglycemia, sweating, and **tremors**, while patients with gastrinoma have inflammation of the esophagus, epigastric **pain**, multiple ulcers, and possibly **diarrhea**. Symptoms of glucagonoma include a distinctive skin rash, inflammation of the stomach, glucose intolerance, weight loss, weakness, and anemia (less common). Patients with vipoma have episodes of profuse, watery diarrhea, even after **fasting**. Somatostatinoma causes mild diabetes, diarrhea/steatorrhea (fatty stools), weight loss, and gallbladder disease. Nonfunctional endocrine tumors frequently produce the same symptoms as cancer of the exocrine pancreas such as abdominal pain, **jaundice**, and weight loss.

Diagnosis

A thorough physical exam is usually performed when a patient presents with the above symptoms, however, functional endocrine tumors of the pancreas tend to be small and are not detected by palpating the abdomen. Once other illnesses such as infection are ruled out, the doctor will order a series of blood and urine tests. The functional endocrine tumors can be identified through increased levels of hormone in the bloodstream.

Functional endocrine tumors can occur in multiple sites in the pancreas and are often small (less than 1 cm), making them difficult to diagnose. Nonfunctional tumors tend to be larger, which makes them difficult to distinguish from tumors of the exocrine pancreas. Methods such as computed tomography (CT) scan and **magnetic resonance imaging** (MRI) are used to take pictures of the internal organs and allow the doctor to determine whether a tumor is present. Somatostatin receptor scintigraphy (trade name OctreoScan) is an imaging system used to localize endocrine tumors, especially gastrinomas and somatostatinomas. **Endoscopic ultrasound** (EUS) is a more sensitive technique that may be used if a CT scan fails to detect a tumor. Endocrine tumors usually have many blood vessels, so **angiography** may be useful in the doctor's assessment and staging of the tumor. Surgical exploration is sometimes necessary in order to locate very small tumors that occur in multiple sites. These techniques also help the doctor evaluate how far the tumor has spread. A biopsy can be taken to confirm diagnosis, but more often, doctors look at the size and local invasion of the tumor in order to plan a treatment strategy.

Treatment

Staging

The staging system for islet cell cancer is still evolving, but the tumors typically fall into three categories: cancers that arise in one location within the pancreas, cancers that arise in several locations within the pancreas, and cancers that have spread to nearby lymph nodes or to other organs in the body.

Surgery is the only curative method for islet cell cancers, and studies have shown that an aggressive surgical approach can improve survival and alleviate symptoms of the disease. As with most forms of cancer, the earlier it is diagnosed, the greater the chance for survival. With the exception of insulinoma, the majority of islet cell tumors are malignant at the time of diagnosis, and more than half are metastatic. However, surgery and **chemotherapy** have been shown to improve the outcome of patients even if they have metastatic disease. Surgery may include partial or total removal of the pancreas, and in patients with gastrinoma, the stomach may be removed as well. Streptozotocin, doxorubicin, and 5-fluorouracil (5-FU) are chemotherapeutic agents commonly used in the treatment of islet cell cancer. Patients may experience **nausea and vomiting** as well as kidney toxicity from streptozotocin, and bone marrow suppression from doxorubicin. Hormone therapy is used to relieve the symptoms of functional tumors by inhibiting excess hormone production. Other techniques may be used to block blood flow to the liver in an attempt to kill the cancer cells that have spread there. Abdominal pain, nausea, **vomiting** and **fever** may result from this type of treatment. Radiation has little if any role in the treatment of islet cell cancer.

Prognosis

Islet cell cancers overall have a more favorable prognosis than cancers of the exocrine pancreas, and the median survival from diagnosis is three and a half years. This is mainly due to their slow-growing nature. Insulinomas have a five-year survival rate of 80% and

WWW.BOOKBAZ.IR

KEY TERMS

Adenocarcinoma—A malignant tumor that arises within the tissues of a gland and retains its glandular structure.

Angiography—Diagnostic technique used to study blood vessels in a tumor.

Biopsy—Removal and microscopic examination of cells to determine whether they are cancerous.

Chemotherapy—Drug treatment administered to kill cancerous cells.

Endocrine—Refers to glands that secrete hormones circulated in the bloodstream.

Endoscopic ultrasonography (EUS)—Diagnostic imaging technique where an ultrasound probe is inserted down a patient's throat to determine if a tumor is present.

Gastrinoma—Tumor that arises from the gastrin-producing cells in the pancreas.

Insulinoma—Tumor that arises from the insulin-producing cells in the pancreas.

Islets of Langerhans—Clusters of cells in the pancreas that make up the endocrine tissue.

gastrinomas have 65%. When malignant, islet cell cancers do not generally respond well to chemotherapy, and the treatment is mainly palliative. Most patients with metastasis do not survive five years. Islet cell cancer tends to spread to the surrounding lymph nodes, stomach, small intestine, and liver.

Prevention

There are no known risk factors associated with sporadic islet cell cancer. Therefore, it is not clear how to prevent its occurrence. Individuals with MEN syndrome or VHL, however, have a genetic predisposition to developing islet cell cancer and should be screened regularly in an effort to catch the disease early.

Elizabeth Pulcini, MSc

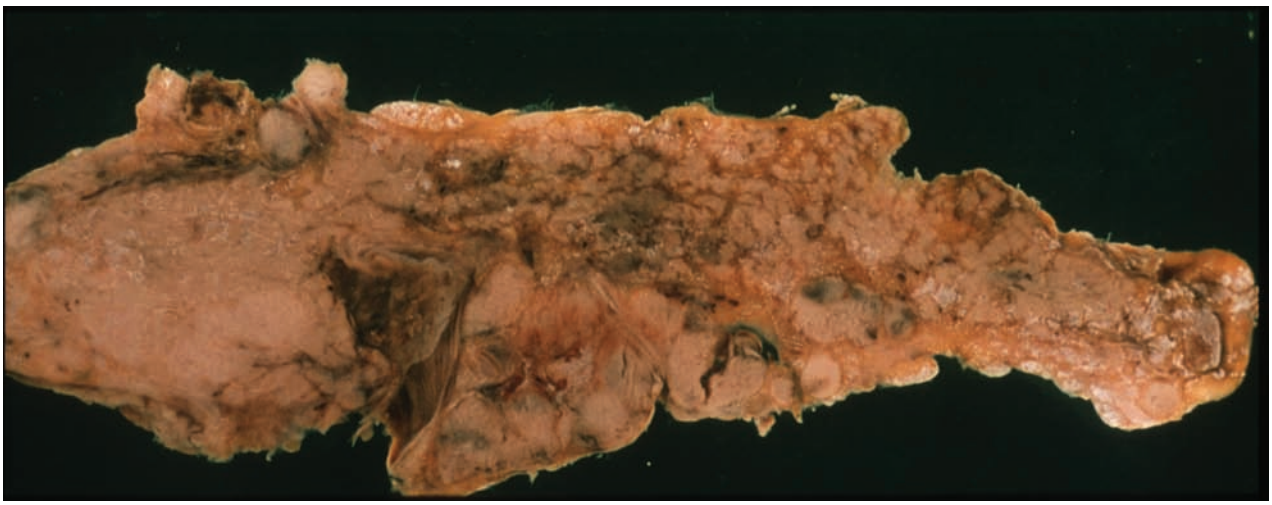
Pancreatic cancer, exocrine

Definition

Exocrine pancreatic cancer is a disease in which cancerous cells originate within the tissues of the pancreas that produce digestive juices.

Description

The pancreas is a 6–8 in (15–20 cm) long, slipper-shaped gland located in the abdomen. It lies behind the stomach, within a loop formed by the small intestine. Other nearby organs include the gallbladder, spleen, and liver. The pancreas has a wide end (head), a narrow end (tail), and a middle section (body). A healthy pancreas is important for normal food digestion and also plays a critical role in the body's metabolic processes. The pancreas has two main functions, and each are performed by distinct types of tissue. The exocrine tissue makes up the vast majority of the gland and secretes fluids into the other organs of the digestive system. The endocrine tissue



Carcinoma of the head of the pancreas. Tumors appear as gritty, gray, hard nodules, invading the adjacent gland. *(Biophoto Associates/Science Source/Photo Researchers, Inc.)*

secretes hormones (like insulin) that are circulated in the bloodstream, and these substances control how the body stores and uses nutrients. The exocrine tissue of the pancreas, comprised mostly of acinar cells and ductal cells, produces pancreatic (digestive) juices. These juices contain several enzymes that help break down proteins and fatty foods. The exocrine pancreas forms an intricate system of channels or ducts, which are tubular structures that carry pancreatic juices to the small intestine where they are used for digestion.

Pancreatic tumors are classified as either exocrine or endocrine tumors depending on which type of tissue they arise from within the gland. Ninety-five percent of pancreatic cancers occur in the tissues of the exocrine pancreas. Ductal adenocarcinomas arise in the cells that line the ducts of the exocrine pancreas and account for 80–90% of all tumors of the pancreas. Unless specified, nearly all reports on pancreatic cancer refer to ductal adenocarcinomas. Less common types of pancreatic exocrine tumors include acinar cell carcinoma, cystic tumors that are typically benign but may become cancerous, and papillary tumors that grow within the pancreatic ducts. Pancreatoblastoma is a very rare disease that primarily affects young children. Two-thirds of pancreatic tumors occur in the head of the pancreas, and tumor growth in this area can lead to the obstruction of the nearby common bile duct that empties bile fluid into the small intestine. When bile cannot be passed into the intestine, patients may develop yellowing of the skin and eyes (**jaundice**) due to the buildup of bilirubin (a component of bile) in the bloodstream. Tumor blockage of bile or pancreatic ducts may also cause digestive problems since these fluids contain critical enzymes in the digestive process. Depending on their size, pancreatic tumors may cause abdominal **pain** by pressing on the surrounding nerves. Because of its location deep within the abdomen, pancreatic cancer often remains undetected until it has spread to other organs such as the liver or lung. Pancreatic cancer tends to rapidly spread to other organs, even when the primary (original) tumor is relatively small.

Though pancreatic cancer accounts for only 3% of all cancers, it is the fifth most frequent cause of cancer deaths. In 2010, an estimated 43,140 new cases of pancreatic cancer were diagnosed in the United States. Pancreatic cancer is primarily a disease associated with advanced age, with 80% of cases occurring between the ages of 60 and 80. Men are almost twice as likely to develop this disease than women. Countries with the highest frequencies of pancreatic cancer include the United States, New Zealand, Western European nations, and Scandinavia. The lowest occurrences of the disease are reported in India, Kuwait and Singapore. African Americans have the highest incidence of pancreatic cancer of any ethnic group worldwide. Whether this difference is due to diet or environmental factors remains unclear.

Causes and symptoms

Although the exact cause for pancreatic cancer is not known, several risk factors have been shown to increase susceptibility to this particular cancer, the greatest of which is cigarette **smoking**. Approximately one-third of pancreatic cancer cases occur among

WWW.BOOKBAZ.IR

smokers. People who have diabetes develop pancreatic cancer twice as often as non-diabetics. Numerous studies suggest that a family history of pancreatic cancer is another strong risk factor for developing the disease, particularly if two or more relatives in the immediate family have the disease. Other risk factors include chronic (long-term) inflammation of the pancreas (**pancreatitis**), **diets** high in fat, and occupational exposure to certain chemicals such as petroleum.

Pancreatic cancer often does not produce symptoms until it reaches an advanced stage. Patients may then present with the following signs and symptoms:

- upper abdominal and/or back pain
- jaundice
- weight loss
- loss of appetite
- diarrhea
- weakness
- nausea

These symptoms may also be caused by other illnesses; therefore, it is important to consult a doctor for an accurate diagnosis.

Diagnosis

Pancreatic cancer is difficult to diagnose, especially in the absence of symptoms, and there is no current screening method for early detection. The most sophisticated techniques available often do not detect very small tumors that are localized (have not begun to spread). At advanced stages where patients show symptoms, a number of tests may be performed to confirm diagnosis and to assess the stage of the disease. Approximately half of all pancreatic cancers are metastatic (have spread to other sites) at the time of diagnosis.

The first step in diagnosing pancreatic cancer is a thorough medical history and complete **physical examination**. The abdomen will be palpated to check for fluid accumulation, lumps, or masses. If there are signs of jaundice, blood tests will be performed to rule out the possibility of liver diseases such as hepatitis. Urine and stool tests may be performed as well.

Non-invasive imaging tools such as computed tomography (CT) scans and **magnetic resonance imaging** (MRI) can be used to produce detailed pictures of the internal organs. CT is the tool most often used to diagnose pancreatic cancer, as it allows the doctor to determine if the tumor can be removed by surgery or not. It is also useful in staging a tumor by showing the extent to which the tumor has spread. During a CT scan, patients receive an intravenous injection of a contrast dye so the organs can be visualized more clearly. MRI may be performed instead of CT if a patient has an allergy to the CT contrast dye. In some cases where the tumor is impinging on blood vessels or nearby ducts, MRI may be used to generate an image of the pancreatic ducts.

If the doctor suspects pancreatic cancer and no visible masses are seen with a CT scan, a patient may undergo a combination of invasive tests to confirm the presence of a pancreatic tumor. **Endoscopic ultrasound** (EUS) involves the use of an **ultrasound** probe at the end of a long, flexible tube that is passed down the patient's throat and into the stomach. This instrument can detect a tumor mass through high frequency sound waves and echoes. EUS can be accompanied by fine needle aspiration (FNA), where a long needle, guided by the ultrasound, is inserted into the tumor mass in order to take a biopsy sample. **Endoscopic retrograde cholangiopancreatography** (ERCP) is a technique often used in patients with severe jaundice because it enables the doctor to relieve blockage of the pancreatic ducts. The doctor, guided by **endoscopy** and x rays, inserts a small metal or plastic stent into the duct to keep it open. During ERCP, a biopsy can be done by collecting cells from the pancreas with a small brush. The cells are then examined under the microscope by a pathologist, who determines the presence of any cancerous cells.

In some cases, a biopsy may be performed during a type of surgery called **laparoscopy**, which is done under general **anesthesia**. Doctors insert a small camera and instruments into the abdomen after a minor incision is made. Tissue samples are removed for examination under the microscope. This procedure allows a doctor to determine the extent to which the disease has spread and decide if the tumor can be removed by further surgery.

An **angiography** is a type of test that studies the blood vessels in and around the pancreas. This test may be done before surgery so that the doctor can determine the extent to which the tumor invades and interacts with the blood vessels within the pancreas. The test requires local anesthesia and a catheter is inserted into the patient's upper thigh. A dye is then injected into blood vessels that lead into the pancreas, and x rays are taken.

In April 2001, doctors at major cancer research institutions such as Memorial Sloan-Kettering Cancer Center in New York were investigating CT angiography, an imaging technique that is less invasive than angiography alone. CT angiography is similar to a standard CT scan, but allows doctors to take a series

of pictures of the blood vessels that support tumor growth. A dye is injected as in a CT scan (but at rapid intervals) and no catheter or **sedation** is required. A computer generates 3D images from the pictures that are taken, and the information is gathered by the surgical team who will develop an appropriate strategy if the patient's disease can be operated on.

Treatment

Staging

After cancer of the pancreas has been diagnosed, doctors typically use a TNM staging system to classify the tumor based on its size and the degree to which it has spread to other areas in the body. T indicates the size and local advancement of the primary tumor. Since cancers often invade the lymphatic system before spreading to other organs, regional lymph node involvement (N) is an important factor in staging. M indicates whether the tumor has metastasized (spread) to distant organs. In stage I, the tumor is localized to the pancreas and has not spread to surrounding lymph nodes or other organs. Stage II pancreatic cancer has spread to nearby organs such as the small intestine or bile duct, but not the surrounding lymph nodes. Stage III indicates lymph node involvement, whether the cancer has spread to nearby organs or not. Stage IVA pancreatic cancer has spread to organs near the pancreas such as the stomach, spleen, or colon. Stage IVB is a cancer that has spread to distant sites (liver, lung). If pancreatic cancer has been treated with success and then appears again in the pancreas or in other organs, it is referred to as recurrent disease.

Treatment of pancreatic cancer will depend on several factors, including the stage of the disease and the patient's age and overall health status. A combination of therapies is often employed in the treatment of this disease to improve the patient's chances for survival. Surgery is used whenever possible and is the only means by which cancer of the pancreas can be cured. However, less than 15% of pancreatic tumors can be removed by surgery. By the time the disease is diagnosed (usually at stage III), therapies such as radiation and **chemotherapy** or both are used in addition to surgery to relieve a patient's symptoms and enhance quality of life. For patients with metastatic disease, chemotherapy and radiation are used mainly as palliative (pain alleviating) treatments.

Surgery

Three types of surgery are used in the treatment of pancreatic cancer, depending on what section of the pancreas the tumor is located in. A Whipple procedure removes the head of the pancreas, part of the small intestine and some of the surrounding tissues. This procedure is most common since the majority of pancreatic cancers occur in the head of the organ. A total **pancreatectomy** removes the entire pancreas and the organs around it. **Distal pancreatectomy** removes only the body and tail of the pancreas. Chemotherapy and radiation may precede surgery (neoadjuvant therapy) or follow surgery (adjuvant therapy). Surgery is also used to relieve symptoms of pancreatic cancer by draining fluids or bypassing obstructions. Side effects from surgery can include pain, weakness, **fatigue**, and digestive problems. Some patients may develop diabetes or malabsorption as a result of partial or total removal of the pancreas.

Radiation therapy

Radiation therapy is sometimes used to shrink a tumor before surgery or to remove remaining cancer cells after surgery. Radiation may also be used to relieve pain or digestive problems caused by the tumor if it cannot be removed by surgery. External radiation therapy refers to radiation applied externally to the abdomen using a beam of high-energy x rays. High-dose intraoperative radiation therapy is sometimes used during surgery on tumors that have spread to nearby organs. Internal radiation therapy refers to the use of small radioactive seeds implanted in the tumor tissue. The seeds emit radiation over a period of time to kill tumor cells. Radiation treatment may cause side effects such as fatigue, tender or itchy skin, nausea, **vomiting**, and digestive problems.

Chemotherapy

Chemotherapeutic agents are powerful drugs that are used to kill cancer cells. They are classified according to the mechanism by which they induce cancer cell death. Multiple agents are often used to increase the chances of tumor cell death. Gemcitabine is the standard drug used to treat pancreatic cancers and can be used alone or in combination with other drugs, such as 5-flourouracil (5-FU). Other drugs are being tested in combination with gemcitabine in several ongoing clinical trials, specifically irinotecan (CPT-11) and oxaliplatin. Chemotherapy may be administered orally or intravenously in a series of doses over several weeks. During treatment, patients may experience fatigue, nausea, vomiting, hair loss, and mouth sores, depending on which drugs are used.

WWW.BOOKBAZ.IR

KEY TERMS

Acinar cell carcinoma—A malignant tumor arising from the acinar cells of the pancreas.

Angiography—Diagnostic technique used to study blood vessels in a tumor.

Biopsy—Removal and microscopic examination of cells to determine whether they are cancerous.

Cancer vaccines—A treatment that uses the patient's immune system to attack cancer cells.

Chemotherapy—Drug treatment administered to kill cancerous cells.

Ductal adenocarcinoma—A malignant tumor arising from the duct cells within a gland.

Endoscopic retrograde cholangiopancreatography (ERCP)—Diagnostic technique used to obtain a biopsy. Also a surgical method of relieving biliary obstruction caused by a tumor.

Endoscopic ultrasonography (EUS)—Diagnostic imaging technique in which an ultrasound probe is inserted down a patient's throat to determine if a tumor is present.

Exocrine—Refers to glands which secrete their products through a duct.

Laparoscopic surgery—Minimally invasive surgery in which a camera and surgical instruments are inserted through a small incision.

Pancreatectomy—Partial or total surgical removal of the pancreas.

Radiation therapy—Use of radioisotopes to kill tumor cells. Applied externally through a beam of x rays, intraoperatively (during surgery), or deposited internally by implanting radioactive seeds in tumor tissue.

Whipple procedure—Surgical removal of the head of the pancreas, part of the small intestine, and some surrounding tissue.

Biological treatments

Numerous vaccine treatments are being developed in an effort to stimulate the body's immune system into attacking cancer cells. This is also referred to as immunotherapy. Another type of biological treatment involves using a targeted monoclonal antibody to inhibit the growth of cancer cells. The antibody is thought to bind to and neutralize a protein that contributes to the growth of the cancer cells. Investigational treatments such as these may be considered by patients with metastatic disease who would like to participate in a clinical trial. Biological treatments typically cause flu-like symptoms (chills, **fever**, loss of appetite) during the treatment period.

Alternatives

Acupuncture or **hypnotherapy** may be used in addition to standard therapies to help relieve the pain associated with pancreatic cancer. Because of the poor prognosis associated with pancreatic cancer, some patients may try special diets with vitamin supplements, certain **exercise** programs, or unconventional treatments not yet approved by the FDA. Patients should always inform their doctors of any alternative treatments they are using as they could interfere with standard therapies. The National Cancer Institute (NCI) is funding phase III clinical trials of a controversial treatment for pancreatic cancer that involves the use of supplemental pancreatic enzymes (to digest cancerous cells) and coffee **enemas** (to stimulate the liver to detoxify the cancer). These theories remain unproven and the study is widely criticized in the medical community. It remains to been seen whether this method of treatment has any advantage over the standard chemotherapeutic regimen in prolonging patient survival or improving quality of life.

Prognosis

Unfortunately, cancer of the pancreas is often fatal, and median survival from diagnosis is less than six months, while the five-year survival rate is 4%. This is mainly due to the lack of screening methods available for early detection of the disease. Yet, even when localized tumors can be removed by surgery, patient survival after five years is only 10–15%. These statistics demonstrate the aggressive nature of most pancreatic cancers and their tendency to recur. Pancreatic cancers tend to be resistant to radiation and chemotherapy and these modes of treatment are mainly used to relieve pain and tumor burden.

Prevention

Although the exact cause of pancreatic cancer is not known, there are certain risk factors that may

increase a person's chances of developing the disease. Quitting smoking will certainly reduce the risk for pancreatic cancer and many other cancers. The American Cancer Society recommends a diet rich in fruits, vegetables, and dietary fiber in order to reduce the risk of pancreatic cancer. According to the NCI, workers who are exposed to petroleum and other chemicals may be at greater risk for developing the disease and should follow their employer's safety precautions. People with a family history of pancreatic cancer are at greater risk than the general population, as a small percentage of pancreatic cancers are considered hereditary.

Pancreatitis

Definition

Pancreatitis is an inflammation of the pancreas, an organ that is important in digestion. Pancreatitis can be acute (beginning suddenly, usually with the patient recovering fully) or chronic (progressing slowly with continued, permanent injury to the pancreas).

Demographics

The incidence of acute pancreatitis is approximately 40 cases per year per 100,000 adults, with the United States and Finland being the two most predominant countries of its occurrence. Mild forms of pancreatitis account for approximately 80% of the cases, with a mortality rate as low as 1%, while severe pancreatitis (approximately 20%) has as high as a 30% rate of mortality. African Americans have the highest incidence (approximately 20.5%), Caucasians approximately 5.5%, and Native Americans, approximately 4% per 100,000 population. The most common age for pancreatitis to occur is between 35–64 years of age.
